Abstract

Convolutional source separation is often done in two stages: 1) estimation of the mixing filters and 2) estimation of the sources. Traditional approaches suffer from the ambiguities of arbitrary permutations and scaling in each frequency bin of the estimated filters and/or the sources, and they are usually corrected by taking into account some special properties of the filters/sources. This paper focusses on the filter permutation problem in the absence of scaling, investigating the possible use of the temporal sparsity of the filters as a property enabling permutation correction. Theoretical and experimental results highlight the potential as well as the limits of sparsity as an hypothesis to obtain a well-posed permutation problem.

Keywords:

sparse filters, convolutional blind source separation, permutation ambiguity, ℓ^p minimization, Hall's Marriage Theorem, bi-stochastic matrices

1. Introduction

Blind source separation and blind source localization are ubiquitous problems in signal processing, with applications ranging from wireless telecommunications to underwater acoustics and sound enhancement.

These problems can be considered as reasonably well understood and solved in simple linear instantaneous settings, where tools such as Independent Component Analysis, as well as techniques exploiting source sparsity, are now mature. However, the convolutive source localization / separation problem remains much more challenging. In particular, without further assumption than statistical independence between sources, the problem is known to be ill-posed because of the so-called frequency permutation (and scaling) problem: at best, one can hope to estimate for each frequency (up to a source and frequency dependent scaling factor) the collection of frequency components of all sources (and of the associated mixing filters); but one cannot match the estimated frequency components from different subbands to globally identify the sources (and mixing filters).

Several practical approaches have been proposed to solve the permutation and scaling problems in practice, by exploiting various properties of either the mixing filters or the sources to match different frequency subbands. While some of these methods may succeed in practice for certain types of sources and filters, there is no known theory guaranteeing the well-posedness of the permutation and scaling problem under appropriate assumptions.

This paper contributes to fill this gap, by exploring well-posedness guarantees for the permutation problem under *sparsity* assumptions on the mixing filters, as well as their limitations. Sparse filters, associated to impulse responses corresponding to a limited set of echoes, are commonly used to model a number of communication channels in various scenarios such as underwater acoustics [1] and wireless telecommunications [2, 3]. Can this sparsity be exploited for blind source localization and separation? A first set of results of this paper (Propositions 1,2,3) shows that, even if the scaling problem is ideally solved, the frequency permutation problem can remain ill-posed for filters that perfectly fit the sparse model with extreme levels of sparsity. In contrast, the main theoretical results achieved in this paper (Theorem 2) show that, when the scaling problem is solved, the frequency permutation problem is well-posed provided that the filters are of prime length and “sufficiently sparse”, where the required level of sparsity depends on the number of sources. Whether the scaling problem itself can be expressed in a well-posed manner remains an open question, as well as the related practical question of designing computationally efficient algorithms to solve it.

1.1. Context and notations

Let $x_i[t]$, $1 \leq i \leq M$ be M mixtures of N source signals $s_j[t]$, resulting from the convolution with filters $a_{ij}[t]$ of length L such that:

$$x_i[t] = \sum_{j=1}^N (a_{ij} \star s_j)[t], \quad 1 \leq i \leq M, \quad (1)$$

where \star denotes convolution. The filter $a_{ij}[t]$ typically models the impulse response between the j^{th} source and the i^{th} sensor. Denoting the Discrete Fourier Transform matrix by $\mathbf{F} = \frac{1}{\sqrt{L}} \left(e^{\frac{2ikl\pi}{L}} \right)_{1 \leq k, l \leq L}$, we will use the common abuse of notation, $\mathbf{F}a_{ij} = \{a_{ij}[\omega]\}_{0 \leq \omega < L}$ to distinguish the frequency coefficients of the filter from the time domain vector $a_{ij} = \{a_{ij}[t]\}_{0 \leq t < L} \in \mathbb{C}^L$. Also, the mixing equation (1) can be rewritten as $\mathbf{X} = \mathbf{A} \star \mathbf{S}$, with \mathbf{A} the matrix of filters

$$\mathbf{A} := (\{a_{ij}[t]\}_{0 \leq t < L})_{1 \leq i \leq M, 1 \leq j \leq N}, \quad (2)$$

\mathbf{X} the observation matrix and \mathbf{S} the source matrix.

In this context, blind filter estimation refers to the problem of obtaining estimates of the filters \mathbf{A} from the mixtures \mathbf{X} , without any explicit knowledge about the sources \mathbf{S} . Mixing filters estimation is relevant for several purposes such as deconvolution, source localization, etc. [4]. It also has a relationship with the problem of Multiple-Input-Multiple-Output (MIMO) system identification in communications engineering [5].

1.2. Frequency domain filter estimation

Estimating the mixing parameters is made easier when all filters are instantaneous, that is to say of length $L = 1$, as the convolution product in (1) coincides with the usual product. However, things get complicated in the general setting of convolutive mixtures.

A common approach for filter estimation then relies on the narrowband approximation [6, 7, 8] to transform the mixing model in Eq. (1) into the time-frequency domain, converting a single convolutive filter estimation problem into several complex instantaneous filter estimation problems. Using standard techniques for instantaneous mixing parameter estimation [7], complex mixing filter coefficients

$$\tilde{\mathbf{A}}[\omega] = \{\tilde{a}_{ij}[\omega]\}_{1 \leq i \leq M, 1 \leq j \leq N} \quad (3)$$

are then estimated for each frequency bin $0 \leq \omega < L$.

1.3. Permutation and scaling ambiguities

Without further assumption on either the filters $a_{ij}[t]$ or the sources $s_j[t]$, one can at best hope to find an estimation $\tilde{\mathbf{A}} = (\tilde{a}_{ij})$ where for every frequency ω we have $\tilde{a}_{ij}[\omega] = \lambda_j[\omega]a_{i\sigma_\omega(j)}[\omega]$, with $\lambda_j[\omega]$ a scaling ambiguity and $\sigma_\omega \in \mathfrak{S}_N$ a permutation ambiguity, where \mathfrak{S}_N is the set of permutations of the integers between one and N . Several methods [6] attempt to solve for these ambiguities by exploiting properties of either the sources \mathbf{S} or the filters \mathbf{A} [9, 10, 11].

1.4. Exploiting sparsity to solve the permutation ambiguity

The focus of this article is the use of the *sparsity* of \mathbf{A} in the time domain to find $\sigma_0, \dots, \sigma_{L-1} \in \mathfrak{S}_N$, assuming the scaling is solved, i.e., $\lambda_j[\omega] = 1$.

Assuming that \mathbf{A} is sparse means that each filter a_{ij} has few nonzero coefficients, as measured by the ℓ^0 “norm”

$$\|a_{ij}\|_0 := \#\{0 \leq t < L, a_{ij}[t] \neq 0\}. \quad (4)$$

We use the quoting marks following the early notations of D. Donoho [12], as a reminder that this is neither a norm nor a quasi norm. The approach considered in this article is to seek permutations $\hat{\sigma}_0, \dots, \hat{\sigma}_{L-1}$ yielding the sparsest estimated time-domain matrix of filters $\hat{\mathbf{A}} = (\hat{a}_{ij})$ where $\hat{a}_{ij}[\omega] := \tilde{a}_{i\hat{\sigma}_\omega(j)}[\omega]$. Besides the ℓ^0 “norm” $\|\hat{\mathbf{A}}\|_0 := \sum_{ij} \|\hat{a}_{ij}\|_0$, the following ℓ^p quasi-norms will be used to quantify the sparsity of $\hat{\mathbf{A}}$:

$$\|\hat{\mathbf{A}}\|_p^p := \sum_{ij} \|\hat{a}_{ij}\|_p^p = \sum_{ijt} |\hat{a}_{ij}[t]|^p, \quad 0 < p \leq 1. \quad (5)$$

1.5. Main results

The main result of this paper (Theorem 2) is a theoretical guarantee that when the filter length L is prime, k -sparse filters (i.e., such that $\|a_{ij}\|_0 \leq k$) uniquely minimize the ℓ^0 “norm” of \mathbf{A} (up to a global permutation) if $\frac{k}{L} \leq \alpha(N)$, where $\alpha(N)$ is a threshold that depends on the number of sources N . To reach this bound we exploit uncertainty principles (Lemma 1, based on Chebotarev’s theorem on roots of unity) as well as the bistochastic structure of the problem through an apparently new quantitative result on bistochastic matrices (Lemma 2, exploiting Hall’s Marriage Theorem).

In the practical setting of orthogonal frequency division multiplexed transmission scheme with pilot symbol assisted modulation, relative sparsity levels

k/L between 0.1 and 0.2 have been reported [2]. These can be compared with the well-posedness thresholds $\alpha(2) = 0.25$ and $\alpha(3) = 0.125$, showing that (from the worst-case perspective considered in this paper), sparsity can be exploited for $N = 2$ sources and possibly for $N = 3$ sources.

1.6. Structure of the paper

The main theorems are stated and proved in Sections 2-3. In Section 4 we discuss the strength of the assumptions used in the theorems, and how much these could be relaxed. In Section 5, a naive combinatorial ℓ^p minimization algorithm is proposed to resolve filter permutations and used for Monte-Carlo simulations. We conclude with a discussion of the potential, as well as the limits, of sparsity as a hypothesis to solve permutation problems, in connection with the theoretical and empirical results. The proofs of all technical lemmata are gathered in the appendix.

2. Theoretical guarantees

Given an $M \times N$ filter matrix \mathbf{A} , made of filters of length L , and L permutations $\sigma_0, \dots, \sigma_{L-1} \in \mathfrak{S}_N$, we let $\tilde{\mathbf{A}}$ be the matrix obtained from \mathbf{A} by applying the permutations in the frequency domain, without scaling

$$\tilde{a}_{ij}[\omega] = a_{i\sigma_\omega(j)}[\omega], \quad (6)$$

The effect of the permutations is said to coincide with that of a global permutation $\pi \in \mathfrak{S}_N$ of the columns of \mathbf{A} if $\tilde{a}_{ij} = a_{i\pi(j)}$, $\forall i, j$, or equivalently in the frequency domain:

$$\tilde{a}_{ij}[\omega] := a_{i\sigma_\omega(j)}[\omega] = a_{i\pi(j)}[\omega], \quad 0 \leq \omega < L, \quad \forall i, j. \quad (7)$$

This is denoted $\mathbf{A} \equiv \tilde{\mathbf{A}}$. To begin with, we show that for filters with disjoint time-domain supports, permutations cannot decrease the ℓ^p quasi-norm, $0 \leq p \leq 1$:

Theorem 1. *Let $\Gamma_{ij} \subset \{0, \dots, L-1\}$ be the time-domain support of a_{ij} . Suppose that for all i and $j_1 \neq j_2$ we have*

$$\Gamma_{i,j_1} \cap \Gamma_{i,j_2} = \emptyset. \quad (8)$$

Then, for $0 \leq p \leq 1$, we have $\|\tilde{\mathbf{A}}\|_p \geq \|\mathbf{A}\|_p$.

Proof First, notice that for each frequency $0 \leq \omega < L$ and channel $i \leq M$, permutations preserve the equality $\sum_j a_{ij}[\omega] = \sum_j \tilde{a}_{ij}[\omega]$. Thus, the same holds in the time-domain : $\sum_j a_{ij} = \sum_j \tilde{a}_{ij}$. By the disjoint supports hypothesis and the triangle inequality satisfied by ℓ^p quasi-norm raised to the p -th power, which defines a proper metric $d(x, y) := \|x - y\|_p^p$, we have

$$\sum_j \|a_{ij}\|_p^p = \left\| \sum_j a_{ij} \right\|_p^p = \left\| \sum_j \tilde{a}_{ij} \right\|_p^p \leq \sum_j \|\tilde{a}_{ij}\|_p^p. \quad (9)$$

We conclude by summing over all channels i . □

Note that filters with disjoint supports need not be very sparse: M filters of length L can have disjoint supports provided that $\max_j \|a_{ij}\|_0 \leq L/M$. Yet, disjointness of filter supports is a strong assumption, and Theorem 1 only indicates that frequency permutations cannot decrease the ℓ^p quasi-norm. Thus, the minimum value of the ℓ^p quasi-norm might not be uniquely achieved (up to a global permutation). In the main result, we consider k -sparse filters of prime length, and $p = 0$:

Theorem 2. *Let \mathbf{A} be an $M \times N$ matrix of filters of prime length L . Assume that*

$$\max_{ij} \|a_{ij}\|_0 \leq k, \quad (10)$$

where

$$\frac{k}{L} \leq \alpha(N) := \begin{cases} \frac{2}{N(N+2)} & \text{if } N \text{ is even,} \\ \frac{2}{(N+1)^2} & \text{if } N \text{ is odd.} \end{cases} \quad (11)$$

Then, up to a global permutation, \mathbf{A} uniquely minimizes the ℓ^0 “norm” among all possible frequency permutations.

3. Proof of Theorem 2

The proof of Theorem 2 relies on a measure of the “amount” of incurred permutation, on uncertainty principles, and on combinatorial arguments related to bi-stochastic matrices, involving Hall’s Marriage Theorem.

3.1. Measures of the amount of incurred permutations

To measure the “amount” of incurred permutations, one could count the number of frequency bands where a non-trivial permutation is incurred, with respect to the best matching global permutation π , i.e., $\min_{\pi} \#\{\omega, \sigma_{\omega} \neq \pi\}$. However, this would generally yield the maximum count $L - 1$.

An alternative is to count the “size” of the incurred permutations, given a reference global permutation π , as the maximum number of frequencies where each estimated filter $\tilde{\mathbf{A}}$ actually differs from the (globally permuted) original filters \mathbf{A} , yielding:

$$\Delta(\tilde{\mathbf{A}}, \mathbf{A}|\pi) := \max_{i,j} \|\mathbf{F}(\tilde{a}_{ij} - a_{i\pi(j)})\|_0 \quad (12)$$

$$\Delta(\tilde{\mathbf{A}}, \mathbf{A}) := \min_{\pi \in \mathfrak{S}_N} \Delta(\tilde{\mathbf{A}}, \mathbf{A}|\pi). \quad (13)$$

Note that $\Delta(\tilde{\mathbf{A}}, \mathbf{A}) = 0$ iff $\tilde{\mathbf{A}} \equiv \mathbf{A}$.

3.2. Exploitation of an uncertainty principle

With this notation, we have the following Lemma:

Lemma 1. *Assume that $\tilde{\mathbf{A}} \not\equiv \mathbf{A}$, that L is a prime integer, and that*

$$2k + \Delta \leq L \quad (14)$$

with $k := \max_{i,j} \|a_{ij}\|_0$. Then $\|\tilde{\mathbf{A}}\|_0 > \|\mathbf{A}\|_0$ and $\|\tilde{a}_{ij}\|_0 \geq \|a_{ij}\|_0, \forall i, j$. The latter inequality is strict when $\tilde{a}_{ij} \neq a_{ij}$. For a general L (not necessarily prime), the same conclusions hold when the assumption (14) is replaced with

$$2k \cdot \Delta < L. \quad (15)$$

The skilled reader will rightly sense the role of uncertainty principles [13, 14, 15] in the above lemma. The case L prime allows to use a consequence of Chebotarev’s theorem on roots of unity, which already lead to theoretical guaranties for exact sparse recovery in the context of linear inverse problems with partial Fourier measurements [16].

3.3. Combinatorial arguments

Using Lemma 1 with prime L , a simple combinatorial argument could be used to obtain a weakened version of Theorem 2, with the more conservative constant $\alpha'(N) := 1/2N!$ [17]. The proof of Theorem 2 with the constant $\alpha(N)$ exploits a stronger universal upper bound $\Delta(\tilde{\mathbf{A}}, \mathbf{A}) \leq L(1 - 2\alpha(N))$, obtained through an apparently new quantitative application of Hall’s Marriage Theorem [18] to bi-stochastic matrices.

Definition 1 (Bi-stochastic matrix). An $N \times N$ matrix \mathbf{B} is called bi-stochastic if all its entries are non-negative, and the sum of the entries over each row as well as the sum of the entries over each column is one.

Lemma 2. Let \mathbf{B} be an $N \times N$ bi-stochastic matrix: there exists a permutation matrix \mathbf{P} such that all the entries of \mathbf{B} on the support of \mathbf{P} exceed the threshold

$$2\alpha(N) = \begin{cases} \frac{4}{N(N+2)} & \text{if } N \text{ is even,} \\ \frac{4}{(N+1)^2} & \text{if } N \text{ is odd.} \end{cases} \quad (16)$$

Corollary 1. Let $\sigma_0, \dots, \sigma_{L-1} \in \mathfrak{S}_N$ be L permutations. There exists a global permutation π such that

$$C_{j\pi(j)} = \#\{\ell : \sigma_\ell(j) = \pi(j)\} \geq 2L\alpha(N), \quad \forall 1 \leq j \leq N. \quad (17)$$

3.4. Proof of Theorem 2

Using the above tools we can now prove Theorem 2. By Corollary 1, there is a permutation π such that for each j , we have

$$\|\mathbf{F}(\tilde{a}_{ij} - a_{i\pi(j)})\|_0 \leq \#\{\ell : \sigma_\ell(j) \neq \pi(j)\} \leq L(1 - 2\alpha(N)), \quad (18)$$

hence $\Delta(\tilde{\mathbf{A}}, \mathbf{A}|\pi) \leq L(1 - 2\alpha(N))$ and finally $\Delta(\tilde{\mathbf{A}}, \mathbf{A}) \leq L(1 - 2\alpha(N))$. Combined with the assumption $k \leq L\alpha(N)$, we obtain $2k + \Delta \leq L$, and we conclude thanks to Lemma 1.

4. Discussion

The reader may have noticed that Theorem 2, while dropping the *disjoint support* assumption from Theorem 1, introduces new restrictions: the assumption that L is prime, and the restriction to $p = 0$ compared to $0 \leq p \leq 1$ in Theorem 1. How important are these restrictions? Could they be relaxed while exploiting sparsity together with the *disjoint support* assumption? This is discussed in this section.

4.1. Extending Theorem 2 to non-prime filter length L ?

As indicated by Proposition 1 below, for even filter length $L \geq 4$, there exists sparse matrices of filters that are the sparsest *but not unique (even up to a global permutation)* solution of the considered problem: certain frequency permutations provide an *equally sparse but not equivalent solution*.

Proposition 1. *For any integer k such that $2k$ divides L , there exists a matrix of k -sparse filters \mathbf{A} and a set of $L/2k$ frequency permutations resulting in $\tilde{\mathbf{A}} \neq \mathbf{A}$ such that for all $0 \leq p \leq \infty$:*

$$\|\tilde{a}_{ij}\|_p = \|a_{ij}\|_p, \quad \forall i, j. \quad (19)$$

We have $2k \cdot \Delta(\tilde{\mathbf{A}}, \mathbf{A}) = L$.

The fact that the filter matrices \mathbf{A} and $\tilde{\mathbf{A}}$ satisfy $2k \cdot \Delta(\tilde{\mathbf{A}}, \mathbf{A}) = L$ shows the sharpness of Lemma 1 for the case when L is even: the strict inequality in (15) cannot be improved.

Specializing Proposition 1 to $k = 1$ for even filter length $L \geq 4$ yields ideally 1-sparse filters a_{ij} and a set of $L/2$ frequency permutations such that: \tilde{a}_{ij} are 1-sparse; the estimated filter $\tilde{\mathbf{A}}$ is not equivalent to the original \mathbf{A} and cannot be discriminated from it by any ℓ^p quasi-norm.

4.2. Stronger guarantees with disjoint supports and sparsity ?

Could one get improved results by combining the disjoint support assumptions from Theorem 1 and the sparsity assumption from Theorem 2 ? For even filter length $L \geq 4$, Proposition 2 below indicates the existence of sparse matrices of filters *with disjoint supports* that are the sparsest but not unique (even up to a global permutation) solution of the considered problem: certain frequency permutations of “size” $\Delta = L/2k$ provide an equally good but not equivalent solution.

Proposition 2. *For any integers $k' < k \leq L/2$ such that $2k'$ divides L , there exists a matrix of k -sparse filters \mathbf{A} with disjoint supports (8), and a set of $L/2k'$ frequency permutations resulting in $\tilde{\mathbf{A}} \neq \mathbf{A}$, such that for all $0 \leq p \leq \infty$: $\|\tilde{\mathbf{A}}\|_p = \|\mathbf{A}\|_p$ and*

$$\|\tilde{a}_{ij}\|_p = \|a_{ij}\|_p, \quad \forall i, j. \quad (20)$$

We have $2k' \cdot \Delta(\tilde{\mathbf{A}}, \mathbf{A}) = L$.

Specializing Proposition 2 to $k' = 1$ and $k = 2$ for even $L \geq 4$ yields 2-sparse filters a_{ij} and a set of $L/2$ frequency permutations such that: \tilde{a}_{ij} are 2-sparse; $\tilde{\mathbf{A}}$ is not equivalent to \mathbf{A} and cannot be discriminated from it by any ℓ^p quasi-norm.

This shows that even by adding the disjoint support assumption, for even $L \geq 4$, there is little margin to improve Lemma 1: at best, one can hope to replace the strict inequality in (15) with a large one. Can this actually be done? This is partially answered by the following results:

Proposition 3. *Assume that $\tilde{\mathbf{A}} \neq \mathbf{A}$, that*

$$2k \cdot \Delta(\tilde{\mathbf{A}}, \mathbf{A}) = L \quad (21)$$

with $k := \max_{ij} \|a_{ij}\|_0$ and that the filters in \mathbf{A} have disjoint supports (8). Then, either $\|\tilde{\mathbf{A}}\|_0 > \|\mathbf{A}\|_0$, or each row of $\tilde{\mathbf{A}}$ is obtained by permuting pairs of distinct filters $a_{ij}, a_{i'j'}$ from the corresponding row of \mathbf{A} such that $a_{ij} - a_{i'j'}$ is proportional to a modulated and translated Dirac comb with $2k$ spikes.

For filter matrices with a single row, since $\tilde{\mathbf{A}} \neq \mathbf{A}$ means that the filters \tilde{a}_{1j} are permuted versions of a_{1j} , we obtain

Corollary 2. *Consider \mathbf{A} with a single row ($M = 1$). Assume that $\tilde{\mathbf{A}} \neq \mathbf{A}$, that*

$$2k \cdot \Delta(\tilde{\mathbf{A}}, \mathbf{A}) = L \quad (22)$$

with $k := \max_{ij} \|a_{ij}\|_0$ and that the filters in \mathbf{A} have disjoint supports (8). Then $\|\tilde{\mathbf{A}}\|_0 > \|\mathbf{A}\|_0$.

4.3. Excessive pessimism?

The counter-examples built in Propositions 1-2, which are associated to Dirac combs, are highly structured. They provide worst case well-posedness bounds, but existing probabilistic versions of uncertainty principles (see, e.g., the nice survey [19]) lead us to conjecture that if the sparse filters in \mathbf{A} are drawn at random (e.g. from Bernoulli-Gaussian distribution), the uniqueness guarantee of Theorem 2 will hold except with small probability $O(L^{-\beta})$, provided that $k < c(\beta)L/\log L$, for large L . This is left to further theoretical investigation.

5. Numerical experiments

The results achieved so far are theoretical well-posedness guarantee, but do not quite provide algorithms to compute the potentially unique (up to global permutation) solution of the frequency permutation problem. We conclude this paper with the description of a relatively naive optimization algorithm, an empirical assessment of its performance with Monte-Carlo simulations, and a discussion of how this compares with the theoretical uniqueness guarantees achieved above.

5.1. Proposed combinatorial algorithm

Given a “permuted” matrix $\tilde{\mathbf{A}}$, one wishes to find a set of frequency permutations yielding a new matrix $\hat{\mathbf{A}}$ with minimum ℓ^p norm.

The proposed algorithm starts from $\hat{\mathbf{A}}_0 = \tilde{\mathbf{A}}$. Given $\hat{\mathbf{A}}_n$, a candidate matrix $\hat{\mathbf{A}}_{n+1,\pi}$ can be obtained by applying a permutation π at frequency $\omega_n \equiv n \pmod{L}$. Testing each possible permutation π and retaining the one π_n which minimizes $\|\hat{\mathbf{A}}_{n+1,\pi}\|_p$ yields the next iterate $\hat{\mathbf{A}}_{n+1} := \hat{\mathbf{A}}_{n+1,\pi_n}$. The procedure is repeated until the ℓ^p quasi-norm $\hat{\mathbf{A}}_n$ ceases to change. Since there is a finite number of permutations to try, the stopping criterion is met after sufficiently many iterations.

5.2. Choice of the ℓ^p criterion

In theory, it could happen that the stopping criterion is only met after a combinatorially large number of iterations. However, the algorithm stops much sooner in practice. In fact, if we were to use the ℓ^0 “norm”, the algorithm would typically stop after just one iteration, because the ℓ^0 “norm” attains its maximum value $M \times N \times L$ for most frequency permutations except a few very special ones. For this reason, we chose to test the algorithm using ℓ^p quasi-norms $p > 0$, which are not as “locally constant” as the ℓ^0 “norm”. To our surprise, the experiments below will show that the best performance is not achieved for small p , but rather for $p = 2 - \epsilon$ with small $\epsilon > 0$. For $p = 0$ and for $p \geq 2$, the algorithm indeed completely fails.

5.3. Monte-Carlo simulations

For various filter lengths L , sparsity levels k and dimensions M, N , random sparse filter matrices \mathbf{A} made of independent random k -sparse filters were generated. Each filter was drawn by choosing: a) a support of size k uniformly at random; b) i.i.d. Gaussian coefficients on this support.

For each configuration (L, k, M, N) , 200 such random matrices \mathbf{A} were drawn. For each \mathbf{A} , independent random frequency permutations were applied to obtain $\tilde{\mathbf{A}}$. The algorithm was then applied to obtain $\hat{\mathbf{A}}$. The performance was measured using the SNR between \mathbf{A} and the best permutation of $\hat{\mathbf{A}}$.

Figure 1 shows the histogram of SNR values achieved for $L = 31$, $1 \leq k \leq L$, $M \in \{1, 2\}$, $N \in \{2, 3, 4\}$, $p = 1$. It shows that the algorithm either completely succeeds up to machine precision (SNR above 300 dB) or completely fails (SNR of the order of 0 dB). For this reason, in the rest of the

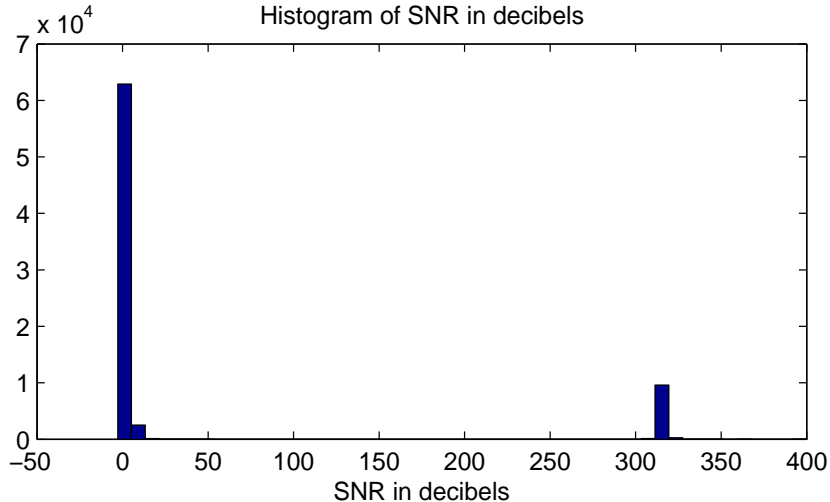

Figure 1: Histogram of SNR between best permutation of $\hat{\mathbf{A}}$ and original \mathbf{A}

experiments the estimation was considered a success when the SNR exceeded 100 dB.

5.4. Role of the ℓ^p criterion

Figure 2 displays the success rate as a function of the relative sparsity k/L , for various choices of the ℓ^p criterion, with filters of prime length $L = 131$, $N = 2$ sources and $M = 5$ channels. The vertical dashed line indicates the threshold $k/L \leq \alpha(2)$ associated with the well-posedness guarantee (using an ℓ^0 criterion) of Theorem 2. Surprisingly, one can observe that the success rate increases when $0 < p < 2$ is increased. The maximum success rate is achieved when $p = 2 - \epsilon$ with small $\epsilon > 0$.

Beyond the well-posedness regime suggested by the theory (i.e., to the right of the vertical dashed line) the algorithm can succeed, but at a rate that rapidly decreases when the relative sparsity k/L increases. In the regime where the problem is proved to be well-posed, the proposed algorithm is often successful but can still fail to perfectly recover the filters, especially –and surprisingly– for small values of k . This phenomenon is strongly marked for $p < 1$ and essentially disappears for $p > 1$. It remains an open question to determine the respective roles of the ℓ^p criterion and of the naive greedy optimization algorithm in this limited performance when the problem is well-posed with respect to the ℓ^0 “norm”.

Figure 2: Filter recovery success as a function of p , $0 \leq p \leq 1.9$

5.5. Role of the filter length L

Figure 3 shows the results for different L values with $p = 1.9$, $M = N = 2$. One can see that the average performance does not seem to depend on whether L is prime or not. As L increases, the performance for “small” k/L slightly increases, but the success rate degrades for “large” k/L close to $\alpha(2)$.

Figure 3: Filter recovery success as a function of L , for $p = 1.9$

5.6. Role of the number of channels M

Figure 4 shows the results for increasing numbers of channels M , with a filter length $L = 512$, $N = 2$ sources, $p = 1.9$. One can observe that the success rate substantially increases when M is increased from $M = 1$ to $M = 2$, and slightly increases as M further increases. Although the worst-case well-posedness guarantees are the same, the algorithm seems to benefit from added filter diversity across channels.

Figure 4: Filter recovery success as a function of M , for $p = 1.9$

5.7. Role of the number of sources N

Figure 5 shows the success rate as a function of the relative sparsity k/L , for $N \in \{2, 3, 4\}$, with $L = 31$, $M = 5$ with $p = 1.9$. The well-posedness limits $k/L \leq \alpha(N)$ associated to Theorem 2 are indicated with vertical dashed lines. The empirical curves confirm that the algorithm can still succeed beyond the worst-case well-posedness guarantees, but with a rapidly decreasing rate of success. When the well-posedness guarantees hold, the algorithm can fail, but its rate of success is high when the relative sparsity is sufficiently small compared to the bound provided by Theorem 2.

Figure 5: Filter recovery success as a function of N , for $p = 1.9$

5.8. Computation time

The algorithm evaluates the ℓ^p quasi-norm of the $N!$ permutations of the sources for each of the L frequencies.

To evaluate the ℓ^p quasi-norm of the filters, the permuted frequency coefficients have to be transformed back into the time domain by inverse Discrete Fourier transform. For each filter, the cost of the Discrete Fourier Transform through a Fast Fourier Transform is $\mathcal{O}(L \log_2 L)$. There are MN filters and hence the cost of ℓ^p quasi-norm evaluation for a given configuration of subbands is $\mathcal{O}(MNL \log_2 L)$.

Hence, the complexity of each sweep through the set of all frequencies is $\mathcal{O}(N!MNL^2 \log_2 L)$. This is rather expensive because the computational cost grows in factorial with the number of sources and in square with the filter length, but it is tractable for small problem sizes and very efficient compared to the brute force approach that would require $\mathcal{O}((N!)^{L-1}MNL \log_2 L)$ operations to test all $(N!)^{L-1}$ possible permutations up to a global permutation.

Figure 6 shows the average computation time over 200 trials for various filter length. The red dashed line corresponds to its prediction using the theoretical cost estimation as $C \times L^2 \log_2 L$ with $C \approx 40$ nanoseconds.

Figure 6: Computation time of the permutation solving algorithm depending on the length L of the filter

6. Conclusions

It is now well known that a sufficient sparsity assumption can be used to guarantee the well-posedness of under-determined linear inverse problems: without the sparsity assumption, the problem admits an affine set of solutions, which intersects at only one point with the set of sparse vectors. Besides this well-posedness property, a key factor that has led to the large deployment of sparse models and methods in various fields of science is the fact that a convex relaxation of the NP-hard ℓ^0 minimization problem can be guaranteed to find this unique solution under certain sparsity assumptions. The availability of efficient convex solvers then really makes the problem tractable.

The problem considered in this paper is not a linear inverse problem. Even though it is a simplification of the original permutation *and scaling* problem arising from signal processing, it remains a priori a much harder problem than linear inverse problems in terms of the structure of the solution set: each solution comes with a herd of solutions that are equivalent up to a global permutation.

The fact that we managed to obtain well-posedness results in this context is encouraging, but this is at best the beginning of the story: without a solution to the scaling problem, this result remains theoretical. Can one

hope to extend these results to the original permutation and scaling problem? Answers to these questions are likely to have an impact in fields such as blind source separation with sparse multipath channels.

A. Proof of Lemma 2 and Corollary 1

A weakened version of Lemma 2, with $2\alpha''(N) = \frac{1}{1+(N-1)^2}$, can be obtained by combining the Birckhoff - Von Neumann theorem and Carathéodory theorem [17]. Yet, this bound is suboptimal. The optimal bound in Lemma 2 follows from Hall's Marriage Theorem, which by the way is also a key ingredient in the proof of the Birkhoff-Von Neumann theorem.

Theorem 3 (Hall's Marriage Theorem [18, 20]). *Let $(A_j)_{j \in J}$ be a family of subsets of a set finite S . There exists a bijection $\pi : J \rightarrow S$ such that $\pi(j) \in A_j$ for all J if, and only if, for all $E \subset J$*

$$\# \cup_{j \in E} A_j \geq \#E. \quad (23)$$

The bijection π is often referred to as a *transversal* for S .

Proof (Lemma 2) For brevity of notation we write α for $\alpha(N)$. \mathbf{B} being the considered bi-stochastic matrix, we wish to exhibit a permutation matrix \mathbf{P} such that $B_{jn} \geq 2\alpha$ for jn on the support of \mathbf{P} . Define the sets $J = S = \llbracket 1, N \rrbracket$, and $A_j := \{n : B_{jn} \geq 2\alpha\}$, $j \in J$, and consider the property

$$\mathcal{P}_k : \forall E \subset J, \#E \leq k \Rightarrow \# \cup_{j \in E} A_j \geq \#E. \quad (24)$$

We wish to prove that \mathcal{P}_k holds true for all $1 \leq k \leq N$: then, by Hall's Marriage Theorem, there exists a bijection $\pi : j \rightarrow \pi(j)$ such that $\pi(j) \in A_j$ for all j , yielding in turn the permutation matrix \mathbf{P} with ones at the entries $(j, \pi(j))$. We proceed by contradiction: assume that \mathcal{P}_N does not hold true. Since \mathcal{P}_1 holds true, without loss of generality, for some $1 \leq k_0 < N$:

$$\# \cup_{1 \leq j \leq k_0} A_j \geq k_0, \text{ and } \# \cup_{1 \leq k \leq k_0+1} A_j \leq k_0. \quad (25)$$

Hence, without loss of generality:

$$\cup_{1 \leq k \leq k_0} A_j = \llbracket 1, k_0 \rrbracket \supset A_{k_0+1}. \quad (26)$$

It follows that for $n > k_0$ and $j \leq k_0 + 1$, we have $n \notin A_j$, hence $B_{jn} < 2\alpha$. Now we use the bi-stochasticity of \mathbf{B} , $\sum_j B_{jn} = \sum_n B_{jn} = 1$, $B_{jn} \geq 0$, to obtain

$$\begin{aligned}
k_0 &\geq \sum_{n \leq k_0} \sum_{j \leq k_0+1} B_{jn} = \sum_{j \leq k_0+1} \sum_{n \leq k_0} B_{jn} \\
&= \sum_{j \leq k_0+1} \left(1 - \sum_{n > k_0} B_{jn}\right) > \sum_{j \leq k_0+1} (1 - (N - k_0)2\alpha) \\
&= (k_0 + 1)(1 - (N - k_0)2\alpha) \\
&= k_0 + \left(1 - (k_0 + 1)(N - k_0)2\alpha\right). \tag{27}
\end{aligned}$$

This implies $2\alpha > 1/(k_0 + 1)(N - k_0)$. However, this yields a contradiction, since a simple functional study shows that

$$\max_{1 \leq k_0 < N} \frac{1}{(k_0 + 1)(N - k_0)} = 2\alpha. \tag{28}$$

□

Equipped with Lemma 2, we can now prove Corollary 1.

Proof (Corollary 1) We consider the matching count matrix \mathbf{C} with entries

$$C_{jn} := \#\{0 \leq \ell < L : \sigma_\ell(j) = n\}, \quad 1 \leq j, n \leq N \tag{29}$$

where $\sigma_\ell, 0 \leq \ell < L$ are the considered permutations. Since $\sum_j C_{jn} = \sum_n C_{jn} = L$ we have $\mathbf{C} = L \cdot \mathbf{B}$ where \mathbf{B} is bi-stochastic, hence there is a permutation π such that $C_{j\pi(j)} \geq 2L\alpha(N)$.

□

We conclude this section by showing the sharpness of Corollary 1 through the construction of permutations that reach the bound. Consider N an integer, and $k_0 := N/2$ (N even) or $k_0 := (N - 1)/2$ (N odd). Let L be a multiple of $(k_0 + 1)(N - k_0)$. Consider the $L \times N$ matrix:

$$\Sigma := \left[\begin{array}{cccccc|ccc}
\mathbf{1} & \mathbf{U} & \mathbf{k}_0 & \dots & \mathbf{2} & & \times & \dots & \times \\
\mathbf{2} & \mathbf{1} & \mathbf{U} & \ddots & \ddots & & \vdots & & \vdots \\
\vdots & \ddots & \ddots & \ddots & \ddots & & \vdots & & \vdots \\
\mathbf{k}_0 & \ddots & \ddots & \ddots & \mathbf{U} & & \vdots & & \vdots \\
\mathbf{U} & \mathbf{k}_0 & \dots & \mathbf{2} & \mathbf{1} & & \times & \dots & \times
\end{array} \right] \tag{30}$$

where: a) the left part, of size $L \times (k_0 + 1)$, is filled with the column vectors $\mathbf{i} \in \mathbb{R}^{L/(k_0+1)}$ made of constant entries equal to the integer $1 \leq i \leq k_0$ and the vector $\mathbf{U} \in \mathbb{R}^{L/(k_0+1)}$ made of the vertical concatenation of the $N - k_0$ column vectors $\mathbf{j} \in \mathbb{R}^{L/(k_0+1)(N-k_0)}$ with constant entries $k_0 + 1 \leq j \leq N$; b) the rows of the the right part, of size $L \times (N - k_0 - 1)$, include exactly once each integer $1 \leq \ell \leq N$ which does not already appear in the corresponding row of the left part. By construction, the L rows of the matrix Σ are associated to L permutations σ_ℓ . We now show that, for any global permutation π , there is at least one column $1 \leq j \leq k_0 + 1$ such that

$$\#\{\ell : \sigma_\ell(j) = \pi(j)\} \leq L/(k_0 + 1)(N - k_0) = L2\alpha(N). \quad (31)$$

Applying again the pigeonhole principle yields: among the $k_0 + 1$ indices j to consider, at least one, j^* , must be mapped to an integer $\pi(j^*) \geq k_0 + 1$. By construction, the columns of Σ are such that column j^* contains at most (in fact: exactly) $L/(k_0 + 1)(N - k_0)$ instances of the value $\pi(j^*)$.

B. Proof of Lemma 1 and Propositions 1 2 3

We prove Lemma 1 first, then the statements of Proposition 1 in the following order: 1), 3), 2). We begin by some notations and fact regarding Dirac combs.

B.1. Dirac combs

Let $p, q \geq 1$ be two integers and $L = pq$ their product. The unit Dirac comb with q spikes and of step p , denoted \mathfrak{m}_p , is the vector of \mathbb{C}^L defined by $\mathfrak{m}_q[t] = 1/\sqrt{q}$ if $t \equiv 0[p]$, $\mathfrak{m}_q[t] = 0$ otherwise. Its Fourier transform is the unit Dirac comb with p spikes and of step q : $\mathbf{F}\mathfrak{m}_q = \mathfrak{m}_p$. For $0 \leq n < p$ an integer translation index and $0 \leq m < q$ an integer modulation index, one can define the translated and modulated Dirac comb $\mathfrak{m}_{q,n,m} = T_n M_m \mathfrak{m}_q$ where T_n is the circular shift by n samples, and M_m is the frequency modulation $(M_m u)[t] := u[t] \cdot e^{2i\pi mt/L}$. One can check that the collection $\{\mathfrak{m}_{q,n,m}\}_{0 \leq n < p, 0 \leq m < q}$ is an orthonormal basis of \mathbb{C}^L .

B.2. Proof of Lemma 1

Let π_0 be the permutation such that $\Delta_0(\mathbf{A}, \tilde{\mathbf{A}}) = \min_{\pi \in \mathfrak{S}_N} \Delta_0(\mathbf{A}, \tilde{\mathbf{A}}|\pi)$. By abuse of notation we still denote \mathbf{A} the matrix obtained by applying π_0 to permute the columns of the original filter matrix. For each channel i and

a source index j such that $a_{ij} = \tilde{a}_{ij}$ we obviously have $\|a_{ij}\|_0 \leq \|\tilde{a}_{ij}\|_0$. Now, since $\Delta_0 \geq 1$ we have $\tilde{\mathbf{A}} \neq \mathbf{A}$ hence there exists a pair i, j such that $\tilde{a}_{ij} \neq a_{ij}$. By the ℓ^0 Dirac-Fourier uncertainty principle [14, Theorem 1], for any vector $u \in \mathbb{C}^L$ we have $\|u\|_0 \|\mathbf{F}u\|_0 \geq L$. Hence, by the hypothesis $k < L/(2\Delta_0)$ we have

$$\|a_{ij}\|_0 + \|\tilde{a}_{ij}\|_0 \geq \|\tilde{a}_{ij} - a_{ij}\|_0 \quad (32)$$

$$\geq L/\|\mathbf{F}(\tilde{a}_{ij} - a_{ij})\|_0 \quad (33)$$

$$\geq L/\Delta_0 > 2k \quad (34)$$

$$\geq \|a_{ij}\|_0 + \|a_{ij'}\|_0 \quad (35)$$

where j' is an arbitrary source index. Hence for every i, j such that $\tilde{a}_{ij} \neq a_{ij}$ and any j' , $\|\tilde{a}_{ij}\|_0 > \|a_{ij'}\|_0$, and we obtain

$$\|\tilde{a}_{ij}\|_0 > \max_{j'} \|a_{ij'}\|_0 \geq \|a_{ij}\|_0. \quad (36)$$

Overall, we have shown that $\|\tilde{\mathbf{A}}\|_0 > \|\mathbf{A}\|_0$.

When L is prime, a stronger uncertainty principle $\|u\|_0 + \|\mathbf{F}u\|_0 \geq L + 1$ holds [15] as an immediate consequence of Chebotarev's theorem on roots of unity.

Theorem 4 (Chebotarev). *Let L be a prime and $1 \leq n \leq L$. Let x_1, \dots, x_n be distinct elements of $\mathbb{Z}/L\mathbb{Z}$, and let $\omega_1, \dots, \omega_n$ also be distinct elements of $\mathbb{Z}/L\mathbb{Z}$. Then the matrix $(\exp(2i\pi x_j \omega_k/L))_{1 \leq j, k \leq n}$ has non-zero determinant.*

Hence, under the assumption $2k + \Delta_0 \leq L$ we can replace (33)-(34) with

$$\dots \geq L + 1 - \|\mathbf{F}(\tilde{a}_{ij} - a_{ij})\|_0 \geq L + 1 - \Delta_0 > 2k \quad (37)$$

to reach the same conclusion.

B.3. Proof of Proposition 1

We shall simply build an example where $\mathbf{A} = [\alpha, \beta]$ is a 1×2 matrix of filters. Extensions to \mathbf{A} an $M \times N$ matrix are trivial by adding mutually distinct sparse columns that are distinct from α and β , and duplicating the first row.

We exploit Dirac combs as described in Appendix B.1. Define $a = \mathfrak{m}_{k,0,0}$, $b = -\mathfrak{m}_{k,L/2k,0}$. The filters a and b have disjoint support and satisfy $\|a\|_0 = \|b\|_0 = k$. Since $a - b = \sqrt{2} \mathfrak{m}_{2k,0,0}$ we have $a[\omega] = b[\omega]$ whenever $\omega \not\equiv 0[2k]$.

Hence, permuting the Fourier transforms of a and b on the $L/2k$ frequencies $\{\omega = 2kr, 0 \leq r < L/2k\}$ yields $\tilde{a} = b$ and $\tilde{b} = a$. Given any $u \in \mathbb{C}^L$ we define perturbations α and β of a and b

$$\begin{cases} \alpha & := a + u \\ \beta & := b + T_{L/2}u \end{cases} \quad (38)$$

with $T_{L/2}$ a circular shift. Noticing that for $\omega = 2kr$

$$(T_{L/2}u)[\omega] = e^{\frac{2i\pi(L/2)\omega}{L}}u[\omega] = e^{2i\pi kr}u[\omega] = u[\omega] \quad (39)$$

we obtain that, after permuting the Fourier transforms of α and β at the frequencies $\omega = 2kr, 0 \leq r < L/2k$,

$$\begin{cases} \tilde{\alpha} & = b + u \\ \tilde{\beta} & = a + T_{L/2}u \end{cases} \quad (40)$$

We choose the vector u to be zero everywhere with two exceptions $u[0] := -a[0]$, $u[\frac{L}{2k}] := -b[\frac{L}{2k}]$. Since $T_{L/2}u \neq u$ and $a \neq b$, we have $\{\alpha, \beta\} \neq \{\tilde{\alpha}, \tilde{\beta}\}$ and $\tilde{\mathbf{A}} \neq \mathbf{A}$. Moreover, $\Delta_0(\tilde{\mathbf{A}}, \mathbf{A}) = \Delta_1(\tilde{\mathbf{A}}, \mathbf{A}) = L/2k$.

Lastly, all considered vectors have k entries of equal magnitude, hence $\|\alpha\|_0 = \|\beta\|_0 = \|\tilde{\alpha}\|_0 = \|\tilde{\beta}\|_0 = k$, and for any $0 < p \leq \infty$ $\|\alpha\|_p = \|\beta\|_p = \|\tilde{\alpha}\|_p = \|\tilde{\beta}\|_p$. In particular, $\|\tilde{\mathbf{A}}\|_p = \|\mathbf{A}\|_p$, $0 \leq p \leq \infty$.

B.4. Proof of Proposition 3

We repeat the construction of the proof of Proposition 1 starting from the Dirac combs $a = \mathfrak{m}_{k',0,0}$, $b = -\mathfrak{m}_{k',L/2k',0}$. Since $k' < k \leq L/2$, we have $\ell := k - k' \leq L/2 - k'$ hence we can choose an ℓ -sparse vector u which support is outside the support of $\mathfrak{m}_{2k'}$ and such that $T_{L/2}u$ and u have disjoint supports. The four vectors $\{a, b, u, T_{L/2}u\}$ have mutually disjoint supports, hence α and β have disjoint supports, $\{\alpha, \beta\} \neq \{\tilde{\alpha}, \tilde{\beta}\}$ and $\tilde{\mathbf{A}} \neq \mathbf{A}$. Moreover, $\Delta_0(\tilde{\mathbf{A}}, \mathbf{A}) = \Delta_1(\tilde{\mathbf{A}}, \mathbf{A}) = L/2k$. Lastly, we have $\|\alpha\|_0 = \|\beta\|_0 = \|\tilde{\alpha}\|_0 = \|\tilde{\beta}\|_0 = k' + \ell = k$, and the ℓ^p norms of these vectors are also equal, hence $\|\mathbf{A}\|_p = \|\tilde{\mathbf{A}}\|_p$, $0 \leq p \leq \infty$.

B.5. Proof of Proposition 2

As in the proof of Lemma 1 we consider \mathbf{A} the permuted matrix associated to the optimal permutation π_0 . Using the inequality $2k \leq L/\Delta_1 \leq L/2\Delta_0$

instead of $2k < L/\Delta_0$ we repeat the steps (32)-(35) to obtain $\|\tilde{a}_{ij}\|_0 \geq \|a_{ij'}\|_0$ for any $j \in E_i := \{j, a_{ij} \neq \tilde{a}_{ij}\}$ and any j' . As a result $\|\tilde{a}_{ij}\|_0 \geq \|a_{ij}\|_0$ for all i, j . The assumption that $\|\tilde{\mathbf{A}}\|_0 = \|\mathbf{A}\|_0$ implies that $\|\tilde{a}_{ij}\|_0 = \|a_{ij}\|_0$ for all i, j .

By assumption, $\tilde{\mathbf{A}} \neq \mathbf{A}$ hence there are indices i, j such that $a_{ij} \neq \tilde{a}_{ij}$. For such i, j , since $\|a_{ij}\|_0 = \|\tilde{a}_{ij}\|_0$, each inequality in (32)-(35) (the inequality $L/\Delta_0 > 2k$ being replaced with $L/\Delta_1 \geq 2k$) must be indeed an equality. This implies that: $\|a_{ij}\|_0 = \|\tilde{a}_{ij}\|_0 = k$; $2k$ divides L and $\Delta_1 = L/2k$; the nonzero vector $b_{ij} := \tilde{a}_{ij} - a_{ij}$ must be an equality case of the ℓ^0 uncertainty principle with $\|b_{ij}\|_0 = 2k$ and $\|\mathbf{F}b_{ij}\|_0 = L/2k$. As a result [15] b_{ij} is a scaled, modulated and translated version of the Dirac comb \mathfrak{w}_{2k} made of $2k$ Diracs spaced every $L/2k$ samples: there exists a scalar $\gamma_{ij} \neq 0$, and two integers $0 \leq n_{ij} < L/2k$, $0 \leq m_{ij} < 2k$ such that

$$b_{ij} = \gamma_{ij} \cdot \mathfrak{w}_{2k, n_{ij}, m_{ij}}. \quad (41)$$

Moreover since $\|a_{ij}\|_0 = \|\tilde{a}_{ij}\|_0 = k$ and $\|\tilde{a}_{ij} - a_{ij}\|_0 = 2k$, the filters \tilde{a}_{ij} and a_{ij} have disjoint supports of size k . Hence, they are the restriction of b_{ij} (resp. of $-b_{ij}$) to their respective supports.

Now, define

$$E_{i,n,m} := \{j \in E_i, n_{ij} = n, m_{ij} = m\}. \quad (42)$$

As observed in the proof of Theorem 1, the equality $\sum_j a_{ij} = \sum_j \tilde{a}_{ij}$ holds, implying $\sum_{j \in E_i} b_{ij} = \sum_j b_{ij} = 0$. Taking inner products with the Dirac comb orthonormal basis $\mathfrak{w}_{2k, n, m}$, $0 \leq n < L/2k$, $0 \leq m < 2k$, yields

$$\sum_{j \in E_{i,n,m}} \gamma_{ij} = 0, \quad (43)$$

Since $\gamma_{ij} \neq 0$, whenever $E_{i,n,m}$ is not empty it contains at least two distinct indices.

By the *disjoint support assumption*: for $j, j' \in E_{i,n,m}$, $j \neq j'$, the original filters a_{ij} and $a_{ij'}$ have disjoint supports. Moreover, we know that these supports are subsets of the support of $\mathfrak{w}_{2k, n, m}$ which is of size $2k$, hence

$$\sharp E_{i,n,m} \cdot k = \left\| \sum_{j \in E_{i,n,m}} a_{ij} \right\|_0 \leq 2k. \quad (44)$$

Hence, whenever $E_{i,n,m}$ is not empty, it contains *exactly* two distinct elements: $E_{i,n,m} = \{j, j'\}$ where $j \neq j'$.

Further, observe that: a) a_{ij} and $a_{ij'}$ have disjoint supports of size k which are subsets of the support of size $2k$ of $\mathfrak{m}_{2k,n,m}$; b) a_{ij} and \tilde{a}_{ij} have the same property. As a result, \tilde{a}_{ij} and $a_{ij'}$ have the same support, which is disjoint from that of a_{ij} . Similarly, a_{ij} has the same support as $\tilde{a}_{ij'}$. Finally, Eq. (43) can be rewritten $\gamma_{ij} + \gamma_{ij'} = 0$, and implies $b_{ij} + b_{ij'} = 0$, that is to say $\tilde{a}_{ij} + \tilde{a}_{ij'} = a_{ij'} + a_{ij}$. We conclude that $\tilde{a}_{ij} = a_{ij'}$ and $\tilde{a}_{ij'} = a_{ij}$.
