Abstract

We study the mobile association problem: we determine the cells corresponding to each base station, i.e, the locations at which intelligent mobile terminals prefer to connect to a given base station rather than to others. This paper proposes a new approach based on optimal transport theory to characterize the solution based on previous works on fluid approximations. We are able to characterize the global optimal solution, as well as the user optimal solution, for the downlink case problem.

1 INTRODUCTION

We consider the case where intelligent mobile terminals, capable of accessing multiple radio access technologies, will decide for themselves the wireless access technology to use and the access point to which to connect. Within this context, we study the mobile association problem, where we determine the locations at which intelligent mobile terminals prefer to connect to a given base station rather than to others.

For the user optimization problem, considering the interactions with other mobile terminals, starting from the seminal paper of Hotelling [1] a large area of research on location games has been developed. His paper [1] introduced the notion of spatial competition in a duopoly situation. Plastria [2] presented an overview of the research on locating one or more new facilities in an environment where competing facilities already exist. Gabszewicz and Thisse [3] provided another general overview on location games. Altman et al. [4] studied the duopoly situation in the uplink case in a line segment and realized that with the particular cost structure that arises in the cellular context more complex cells are obtained at equilibrium. Our work focuses on the downlink case and in a more general situation where a finite number of base stations can compete in a one-dimensional and two-dimensional case without any assumption on the symmetry of the users location. In order to do that, we propose a new framework for mobile association problems using optimal transport

Table 1: Notation

N	Total number of MTs in the network
K	Total number of BSs
f	Deployment distribution of MTs
(x_i, y_i)	Position of the i -th BS
C_i	Cell determined by the i -th BS
N_i	Number of MTs associated to the i -th BS
M_i	Number of carriers offered by the i -th BS
κ_i	Penalization function of non-service
h_i	Channel gain function over the i -th cell
ξ_i	Path loss exponent over the i -th cell

theory (See [5] and references therein), a theory initiated by Monge [6] and Kantorovich [7] that has prove to be useful on many economical context [8, 9, 10]. There is a number of papers on “optimal transport” (see [11], and reference therein) however the authors in [11] consider an optimal selection of routes but do not use the rich theory of optimal transport. The works on stochastic geometry are similar to our analysis of wireless networks (see e.g. [12] and reference therein) but in our case we do not consider any particular deployment distribution function. Fluid models allow us to have this general deployment distribution function.

The remaining of this paper is organized as follows. Section 2 presents the formulation of the problem of minimizing the total power of the network under quality of service constraints. We address the problem for the downlink case where we considered two different policies: round robin scheduling policy (also known as time fair allocation policy) and rate fair allocation policy which are defined in Section 2 and studied precisely in Section 3 and Section 4 with uniform and non-homogeneous distribution of users. In Section 5 we give numerical examples in both one-dimensional and two-dimensional mobile terminals distribution. Section 6 concludes the paper.

2 The Model

A summary of the notation used on this work can be found in Table 1. We consider a network deployed on a region, denoted by D , over the plane. The mobile terminals (MTs) are distributed according to a given deployment distribution function $f(x, y)$. To fix ideas, if the considered region is a square $D = [0 \text{ km}, 1 \text{ km}] \times [0 \text{ km}, 1 \text{ km}]$ and the distribution of the users is uniform $f(x, y) = 1$,

then the proportion of users in the sub-region $\mathcal{A} = [0 \text{ km}, 1/2 \text{ km}] \times [0 \text{ km}, 1/2 \text{ km}]$ is

$$\frac{\iint_{\mathcal{A}} f(x, y) dx dy}{\iint_{\mathcal{D}} f(x, y) dx dy} = \frac{\text{Area}(\mathcal{A})}{\text{Area}(\mathcal{D})} = 1/4.$$

The first equality is obtained because the distribution of the users is uniform. However, the expression at the left-hand side is general and it is always equal to the proportion of mobiles in a sub-region \mathcal{A} . To simplify the notation, we scale the function f such that

$$\iint_{\mathcal{D}} f(x, y) dx dy = 1.$$

Consequently, the function f is a measure of the proportion of users over the network.

In the network, there are K base stations (BSs), denoted by $\text{BS}_i, i \in \{1, \dots, K\}$, located at positions $(x_i, y_i), i \in \{1, \dots, K\}$. We assume for the downlink case (transmission from BSs to MTs) that between neighboring BSs, they transmit in orthogonal channels (such as in OFDMA). Furthermore, we assume that the interference between BSs that are far from each other using the same sub-carrier is small. Consequently, instead of considering the SINR (Signal to Interference plus Noise Ratio), we consider as performance measure the SNR (Signal to Noise Ratio). We denote by C_i the set of mobiles associated to the i -th BS and by N_i the number of mobiles within that cell, both quantities to be determined. If the number of mobiles is greater than the maximum number of carriers available in the i -th cell, denoted by Max_i , we consider a penalization cost function given by

$$\kappa_i(N_i) = \begin{cases} 0 & \text{if } N_i \leq \text{Max}_i, \\ \bar{\kappa}_i(N_i - \text{Max}_i) & \text{if } N_i > \text{Max}_i. \end{cases}$$

We assume that $\bar{\kappa}_i$ can be either a constant or a non-decreasing function¹. We first study the case $N_i \leq M$ and we study the general case in Section 3.

The power transmitted from BS_i to a MT located at position (x, y) , is $P_i(x, y)$ and the power received at the MT is $P_i(x, y)h_i(x, y)$. We shall further assume that the channel gain corresponds to the path loss given by $h_i(x, y) = (\sqrt{R^2 + d_i(x, y)^2})^{-\xi}$ where ξ is the path loss exponent, R is the height of the base station, and $d_i(x, y)$ is the distance between a MT at position (x, y) and BS_i located at (x_i, y_i) , *i.e.*, $d_i(x, y) = \sqrt{(x_i - x)^2 + (y_i - y)^2}$. The SNR received at mobile terminals at position (x, y) in cell C_i is given by $\text{SNR}_i(x, y) = P_i(x, y)h_i(x, y)/\sigma^2$, where σ^2 is the noise power. We assume that the instantaneous mobile throughput is given by the following expression, which is based on Shannon's capacity theorem:

$$\theta_i(x, y) = \log(1 + \text{SNR}_i(x, y)).$$

We want to satisfy an average throughput for MTs located at position (x, y) given by $\bar{\theta}(x, y) > 0$. We shall consider for this objective two policies defined in [13]: (A) *Round robin scheduling policy*: under this policy, each BS devotes an equal fraction of time for transmission to each MT associated to it, and (B) *Rate fair allocation policy*: under this policy, each base station BS maintains a constant power sent to the mobile terminals within its cell. However, each base station modifies the fraction of time allowed to mobile terminals with different channel gains, in order that the average transmission rate demand is satisfied. For more information about this type of policies in the one dimensional case, see [13].

¹For example, the maximum number of possible carriers in Wi-Max is around 2048, so by using this technology we have $\text{Max}_i = 2048$.

2.1 Round robin scheduling policy: Global Optimization

Following this policy, BS_i devotes an equal fraction of time for transmission to MTs located within its cell C_i . The number of MTs located in the i -th cell is N_i . As BS_i divides its time of service proportional to the quantity of users within its cell, then the throughput following the round robin scheduling policy is given by $\theta_i^{\text{RR}}(x, y) = \theta_i(x, y)/N_i$. In order to satisfy a throughput $\bar{\theta}(x, y)$ under this policy $\theta^{\text{RR}}(x, y) \geq \bar{\theta}(x, y)$, or equivalently, in terms of the power

$$P_i(x, y) \geq \frac{\sigma^2}{h_i(x, y)} (2^{N_i \bar{\theta}(x, y)} - 1).$$

As our objective function is to minimize the total power of the network, the constraint will be reached, and we obtain

$$P_i(x, y) = \sigma^2 (2^{N_i \bar{\theta}(x, y)} - 1) ([R^2 + d_i^2(x, y)]^{1/2})^{+\xi}. \quad (1)$$

From last equation we can observe that: i) if the quantity of mobile terminals increases within the cell, it will need to transmit more power to each of the mobile terminals. The reason to do that is because the base station is dividing each time-slot into mini-slots with respect to the number of the mobiles within its cell, and ii) the function $(R^2 + d_i^2(x, y))^{\xi/2}$ on the right hand side give us the dependence of the power with respect to the distance between the base station and the mobile terminal located at position (x, y) .

Our objective is to find the optimal mobile association in order to minimize the total power of the network. Then as the total power

$$P_{\text{total}} = \sum_{i=1}^K P_i^{\text{intra}},$$

where $P_i^{\text{intra}} = \iint_{C_i} P_i(x, y) f(x, y) dx dy,$

P_i^{intra} is the intracell power consumption in cell C_i .

The global optimization for the mobile association problem, that we denote (RR), is to determine the cells $C_i, i \in \{1, \dots, K\}$, to minimize the total power of the network:

$$\text{Minimize } \sum_{i=1}^K \iint_{C_i} P_i(x, y) f(x, y) dx dy$$

subject to (1), where $f(x, y)$ is the deployment distribution function of the users. We solve this problem in Section 3.

2.2 Rate fair allocation policy: User Optimization

In the rate fair allocation policy, each BS will maintain a constant power sent to MTs within its cell, *i.e.*, $P_i(x, y) = P_i$ for each MT at location (x, y) inside cell C_i . However, the BS modifies the

fraction of time allotted to MTs, set in a way such that the average transmission rate to each MT with different channel gain is the same, denoted by $\Theta(x, y)$, for each mobile located at position (x, y) .

Let r_i be the fixed rate of MTs located inside cell C_i . Following the rate fair allocation policy, the rate r_i is given by (see e.g. [13]):

$$r_i = \left(\iint_{C_i} \frac{1}{\log(1 + \text{SNR}_i(x, y))} f(x, y) dx dy \right)^{-1} \beta.$$

We seek for an equilibrium in the game in which each mobile terminal chooses from which base station is served and given the interactions with the other mobile terminals it doesn't have any incentive to change its strategy lonely. Similar notion of equilibrium has been studied in the context of large number of small players in road-traffic theory by Wardrop [14].

Definition.- The Wardrop equilibrium is given in the context of cellular systems by:

$$\text{If } \iint_{C_i} f(x, y) dx dy > 0, \text{ then } \theta_i = \max_{1 \leq j \leq K} \theta_j(C_j), \quad (2a)$$

$$\text{else if } \iint_{C_i} f(x, y) dx dy = 0, \text{ then } \theta_i \leq \max_{1 \leq j \leq K} \theta_j(C_j). \quad (2b)$$

A Wardrop equilibrium is the analog of a Nash equilibrium for the case of a large number of small players, where, in our case, we consider the mobile terminals as the players. In this setting, the Wardrop equilibrium indicates that if there is a positive proportion of mobile terminals associated to the i -th base station (the left-hand side condition in (2a)), then the throughput that the mobile terminals obtain is the maximum that they would obtain from any other base station (right-hand side consequence in (2a)). The second condition indicates that if there is one base station that doesn't have any mobile terminal associated to it (left-hand side condition in (2a)), it is because the mobile terminals can obtain more throughput by connecting with one of the other base stations (right-hand side consequence in (2a)).

We assume that each base station is serving at least one mobile terminal, (if that is not the case, we remove the base station that is not serving any mobile terminal). Then, the equilibrium situation is given by

$$\theta_1 = \theta_2 = \dots = \theta_K.$$

To understand this equilibrium situation, consider as an example the simple case of two base stations: BS₁ and BS₂. Assume that BS₁ offers more throughput than BS₂. Then, the mobile terminals being served by BS₂ will have an incentive to connect to BS₁. The transmitted throughput depends inversely on the quantity of mobiles connected to the base station. As more mobile terminals try to connect to base station BS₁ the throughput will diminish until arrive to the equilibrium where both base stations will offer the same throughput.

The condition $\theta_1 = \theta_2 = \dots = \theta_K$ is equivalent in our setting to $r_1 = r_2 = \dots = r_K$. Let us denote by r to the rate offered by the base station at equilibrium, *i.e.*, $r := r_1 = r_2 = \dots = r_K$. Then, as long as we are in the low-SNR regime, by using the low-SNR approximation of throughput, *i.e.*, the throughput of a mobile at \mathbf{x} is $\log(1 + \text{SNR}) \approx \text{SNR}$, we have that:

$$P_i(C_i) = \frac{r}{\Theta} \iint_{C_i} \sigma^2 (R^2 + d_i^2(x, y))^{\xi/2} f(x, y) dx dy. \quad (3)$$

We want to choose the optimal mobile assignment in order to minimize the total power of the network under the constraint that the mobile terminals have an average throughput of θ , *i.e.*,
Minimize $_{C_i} P_{\text{total}} = \sum_{i=1}^K P_i^{\text{intra}}$

Then our problem reads

$$(RF) \quad \text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \sigma^2 (R^2 + d_i^2(x, y))^{\xi/2} f(x, y) dx dy.$$

We will solve this problem in Section 4.

Thanks to optimal transport theory we are able to characterize the partitions on very general settings. For doing so, consider locations $(x_1, y_1) \dots, (x_K, y_K)$, the Euclidean distance $d_i(x, y) = \sqrt{(x - x_i)^2 + (y - y_i)^2}$, and F a continuous function.

Theorem 2.1. *Consider the problem (P1)*

$$\text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \left[F(d_i(x, y)) + s_i \left(\iint_{C_i} f(\omega, z) d\omega dz \right) \right] f(x, y) dx dy,$$

where C_i is the cell partition of D . Suppose that s_i are continuously differentiable, non-decreasing, and convex functions. The problem (P1) admits a solution that verifies

$$(S1) \quad \begin{cases} C_i = \{x : F(d_i(x, y)) + s_i(N_i) + N_i \cdot s'_i(N_i) \\ \leq F(d_j(x, y)) + s_j(N_j) + N_j \cdot s'_j(N_j)\} \\ N_i = \iint_{C_i} f(\omega, z) d\omega dz. \end{cases}$$

Proof.- See Appendix A

Theorem 2.2. *Consider the problem (P2)*

$$\text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \left[F(d_i(x, y)) \cdot m_i \left(\iint_{C_i} f(\omega, z) d\omega dz \right) \right] f(x, y) dx dy$$

where C_i is the cell partition of D . Suppose that m_i are derivable. The problem (P2) admits a solution that verifies

$$(S2) \quad \begin{cases} C_i = \{x : m_i(N_i)F(d_i(x, y)) f(x, y) + U_i(x, y) \\ \leq m_j(N_j)F(d_j(x, y)) f(x, y) + U_j(x, y)\} \\ U_i = m'_i(N_i) \iint_{C_i} F(d_i(x, y)) f(x, y) dx dy \\ N_i = \iint_{C_i} f(\omega, z) d\omega dz. \end{cases}$$

Proof.- See Appendix B

Notice that in problem (P1) if the functions $s_i \equiv 0$ the solution of the system (S1) becomes the well known Voronoi cells. In problem (P2) if we have that the functions $h_i \equiv 1$ we find again the Voronoi cells. However in all the other cases the Voronoi configuration is not optimal.

Figure 1: Wardrop Equilibrium: Thresholds determining the cell boundaries as a function of the location of the base stations. The network is deployed over the interval $[-10, 10]$ (one-dimensional case) presented here vertically. We consider a uniform distribution of MTs and we find the threshold (blue line) determining the cell boundaries as a function of the base stations positions (red points) by changing the position of one of them. BS_1 is fixed at position 0 and we change the position of BS_2 from -10 to $+10$.

3 Round Robin Scheduling Policy

We assume that a service provider wants to minimize the total power of the network while maintaining a certain average throughput of θ to each mobile terminal of the system using the round robin scheduling policy given by problem (RR)

$$\text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \sigma^2 (R^2 + d_i(x, y)^2)^{\xi/2} (2^{N_i \theta} - 1) f(x, y) dx dy.$$

We see that this problem is an optimal transportation problem (P1) with cost function given by

$$F(d_i(x, y)) = \sigma^2 (R^2 + d_i(x, y)^2)^{\xi/2} \quad \text{and} \\ m_i(x, y) = (2^{N_i \theta} - 1).$$

Proposition.- There exist a unique optimum given by

$$C_i = \left\{ x_0 \in D : d_i(x_0, y_0)^p + h_i(N_i) + N_i h'_i(N_i) \right. \\ \left. \leq d_j(x_0, y_0)^p + k_j(N_j) + N_j k'_j(N_j), \forall j \neq i \right\} \\ N_i = \iint_{C_i} f(x_0, y_0) dx_0 dy_0$$

Let's see a direct application of our results:

Example 3.1. Consider a network of $N = 2500$ mobile terminals distributed according to $f(x)$ in $[0, L]$ (for example, with $L = 5.6$ miles for WiMaX radius cell). We consider two base stations at position $BS_1 = 0$ and $BS_2 = L$ and $R = 1$. Then, the mobile association threshold (the boundary between both cells, i.e., the location at which the mobile terminals obtain the same throughput by connecting to any of both base stations) is reduced to find x such that the following equality holds:

$$\begin{aligned} (2^{N_1\theta} - 1)(1 + x^2)f(x) + 2^{N_1\theta}\theta \log 2 \left[x + \frac{x^3}{3} \right] = \\ (2^{N_2\theta} - 1)(1 + (1 - x)^2)f(x) \\ + 2^{N_2\theta}\theta \log 2 \left[\frac{4}{3} - 2x + x^2 - \frac{x^3}{3} \right] \end{aligned}$$

This is a fixed point equation on x .

If the mobile terminals are distributed uniformly, the optimal solution is given by $C_1 = [0, 1/2 L]$ and $C_2 = [1/2 L, L]$, which is the solution that Voronoi cells would give us and the number of mobile terminals connected to each base station is given by

$$N_1 = N_2 = 1250.$$

However, if the deployment distribution of the mobile terminals is more concentrated near BS_2 than BS_1 , consider for example $f(x) = 2x$, the optimal solution is given by $C_1 = [0, q]$ and $C_2 = [q, L]$ with $q = 0.6027 L$ and

$$N_1 = 908 \quad \text{and} \quad N_2 = 1592.$$

Notice that in the global optimization solution, the number of mobile terminals connected to BS_1 is smaller than the number of mobile terminals connected to BS_2 . However, the cell size is bigger.

4 Rate fair allocation policy

In this framework we give the possibility to mobile terminals to connect to the base station they prefer in order to minimize their power cost function while maintaining an average throughput of θ . This is the reason why we denote this type of network as *hybrid network*.

As we saw this problem is equivalent to

$$(RF) \quad \text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \sigma^2(R^2 + d_i^2(x, y))^{\xi/2} f(x, y) dx dy.$$

Notice that this problem is equivalent to (P1) where the functions $s_i \equiv 1$. The problem has then a solution given by

Proposition.- There exist a unique optimum given by

$$\begin{aligned} C_i &= \left\{ x \in D : \sigma^2(R^2 + d_i^2(x_0, y_0))^{\xi/2}, \right. \\ &\quad \left. \leq \sigma^2(R^2 + d_j^2(x_0, y_0))^{\xi/2}, \forall j \neq i \right\} \\ N_i &= \iint_{C_i} f(x_0, y_0) dx_0 dy_0 \end{aligned}$$

which is the Voronoi cells.

Figure 2: Wardrop Equilibrium in the Non-homogeneous case: The network is deployed over the interval $[-10, 10]$ (one-dimensional case) presented here vertically. We find the threshold (blue line) determining the cell boundaries as a function of the base stations positions (red points) by changing the position of one of them. BS_1 is fixed at position 0 and we change the position of BS_2 from -10 to $+10$. The deployment distribution of the MTs is given by $f(x) = (L - x)/2L^2$.

Figure 3: Wardrop Equilibrium with Multiple Base Stations: The grid area network is the interval $[-10, 10]$ presented here vertically. We consider a uniform distribution of MTs. We find the threshold (blue line) determining the cell boundaries as a function of the base stations positions (red lines) by changing the position of one of them. BS_1 is fixed at position -10 and BS_2 is fixed at position 10 and we change the position of BS_3 from -10 to $+10$.

Figure 4: Wardrop Equilibrium in the 2D case: The grid area network is the square $[-4, 4] \times [-4, 4]$. We set the noise parameter $\sigma = 0.3$ and we set four BSs at positions $BS_1 = (-3, -3)$ $BS_2 = (3, -3)$ $BS_3 = (3, 3)$ $BS_4 = (-3, 3)$ and one at the origin $BS_5 = (0, 0)$. We determine the cell boundaries (deep lines) for the uniform distribution of users

5 Validation of our theoretical model

5.1 One-dimensional case

We first consider the one-dimensional case and we consider a uniform distribution of users in the interval $[-10, 10]$. We set the noise parameter $\sigma = 0.3$. In Fig. 1, we fix one base station BS_2 at position 0 and take as parameter the position of base station BS_1 . We consider the path loss exponent of $\xi = 2$. Red lines shows the positions of the BSs. We are able to determine the cell boundary (solid blue curve) from BS_1 and BS_2 at different positions. In Fig. 3 we fix two base stations $BS_1 = -10$ and $BS_2 = 10$ and we take as parameter the position of base station BS_3 . Red lines shows the positions of the BSs. We determine the cell boundary (solid blue curve) from BS_1 and BS_3 and the cell boundary (dashed blue curve) from BS_2 and BS_3 .

5.2 Two-dimensional case: Uniform and Non-Uniform distribution of users

We consider the two-dimensional case. We consider the square $[-4, 4] \times [-4, 4]$ and the noise parameter $\sigma = 0.3$. We set five base stations at positions $BS_1 = (-3, -3)$, $BS_2 = (3, -3)$, $BS_3 = (-3, 3)$, $BS_4 = (3, 3)$, and $BS_5 = (0, 0)$. We determine the cell boundaries for the uniform distribution of MTs (see Fig. 4) and we compare it to the cell boundaries for the non-uniform distribution of MTs given by $f(x, y) = (L^2 - (x^2 + y^2))/K$ where K is a normalization factor. The latter situation can be interpreted as the situation when mobile terminals are more concentrated in the center and less concentrated in suburban areas as in Paris, New York or London. We observe that the cell size of

Figure 5: Wardrop Equilibrium in 2D Non-Homogeneous Case. The grid area network is the square $[-4, 4] \times [-4, 4]$. We set the noise parameter $\sigma = 0.3$ and we set four BSs at positions $BS_1 = (-3, -3)$ $BS_2 = (3, -3)$ $BS_3 = (3, 3)$ $BS_4 = (-3, 3)$ and one at the origin $BS_5 = (0, 0)$. We determine the cell boundaries (deep lines) for the non-uniform distribution of users given by $f(x, y) = (L^2 - (x^2 + y^2))/K$ where K is a normalization factor. The latter situation takes into account when mobile terminals are more concentrated in the center and less concentrated in suburban areas.

the base station BS_5 at the center is smaller than the others at the suburban areas. This can be explained by the fact that as the density of users is more concentrated in the center the interference is greater in the center than in the suburban areas and then the SINR is smaller in the center. However the quantity of users is greater than in the suburban areas.

6 Conclusions

We have studied a downlink mobile association game. We determined the location at which intelligent mobile terminals prefer to connect to a given base station rather than to others. Thanks to our proposed approach using optimal transport theory for mobile association we are able to completely characterize the mobile association and the cell formation under different policies from the mobile terminals point of view and as well as from the global system point of view.

Appendix A

Theorem 6.1. *Consider the problem (P1)*

$$\text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \left[F(d_i(x, y)) + s_i \left(\iint_{C_i} f(\omega, z) d\omega dz \right) \right] f(x, y) dx dy,$$

where C_i is the cell partition of D . Suppose that s_i are continuously differentiable, non-decreasing, and convex functions. The problem (P1) admits a solution that verifies

$$(S1) \begin{cases} C_i = \{x : F(d_i(x, y)) + s_i(N_i) + N_i \cdot s'_i(N_i) \\ \leq F(d_j(x, y)) + s_j(N_j) + N_j \cdot s'_j(N_j)\} \\ N_i = \iint_{C_i} f(\omega, z) d\omega dz. \end{cases}$$

Proof.- The proof is based mainly from Proposition 3.5 of Crippa et al. [15]. We first define a slightly more general relaxed formulation of the Monge problem:

$$W_F(\mu, \nu) := \inf \left\{ \left(\int_{D \times D} F(d_i(x, y)) d\gamma(x, y) \right) : \gamma \in \Pi(\mu, \nu) \right\}$$

where μ and ν are probability measures, and $\Pi(\mu, \nu)$ is the set of probability measures such that $\pi_1(\gamma) = \mu$ and $\pi_2(\gamma) = \nu$ where π_1 is the projection on the first component and π_2 is the projection on the second component.

We define also the unit simplex in \mathbb{R}^k :

$$S = \left\{ c = (c_1, \dots, c_k) \in \mathbb{R}^k : c_i \geq 0, \sum_{i=1}^k c_i = 1 \right\}$$

The following step is to prove that

$$\begin{aligned} \text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \left[F(d_i(x, y)) + s_i \left(\iint_{C_i} f(\omega, z) d\omega dz \right) \right] f(x, y) dx dy, \\ = \inf_{c \in S} \left\{ W_F(f, \sum_{i=1}^k c_i \delta_{x_i}) + \sum_{i=1}^k s_i(c_i) c_i \right\} \end{aligned}$$

But this holds by Theorem 2.1 and by Remark 2.2 of [15].

In Proposition 3.5 by replacing $|x - x_j|$ by $F(d_j(x, y))$ we obtain the thesis.

Then we check that this partition is an optimum.

Appendix B

Theorem 6.2. Consider the problem (P2)

$$\text{Min}_{C_i} \sum_{i=1}^K \iint_{C_i} \left[F(d_i(x, y)) \cdot m_i \left(\iint_{C_i} f(\omega, z) d\omega dz \right) \right] f(x, y) dx dy$$

where C_i is the cell partition of D . Suppose that m_i are derivable. The problem (P2) admits a solution that verifies

$$(S2) \begin{cases} C_i = \{x : m_i(N_i)F(d_i(x, y))f(x, y) + U_i(x, y) \\ \leq m_j(N_j)F(d_j(x, y))f(x, y) + U_j(x, y)\} \\ U_i = m'_i(N_i) \iint_{C_i} F(d_i(x, y))f(x, y) dx dy \\ N_i = \iint_{C_i} f(\omega, z) d\omega dz. \end{cases}$$

Proof.- The proof is similar to Appendix A.
