## ABSTRACT

Diffusion MRI (dMRI) is used to characterize the directionality and microstructural properties of brain white matter (WM) by measuring the diffusivity of water molecules. In clinical practice the number of dMRI samples that can be obtained is limited, and one often uses short scanning protocols that acquire just 32 to 64 different gradient directions using a single gradient strength (b-value). Such 'single shell' scanning protocols restrict one to use methods that have assumptions on the radial decay of the dMRI signal over different b-values, which introduces estimation biases. In this work we show, that by simply spreading *the same number of samples* over multiple b-values (i.e. multi-shell) we can accurately estimate both the WM directionality using 3D-SHORE and characterize the radially dependent diffusion microstructure measures using MAP-MRI. We validate our approach by undersampling both noisy synthetic and human brain data of the Human Connectome Project, proving this approach is well-suited for clinical applications.

**Index Terms**— MAP-MRI, 3D-SHORE, Sparsity, Estimation Bias, Clinical Applications

## 1. INTRODUCTION

Diffusion MRI (dMRI) is used to characterize the directionality and microstructural properties of brain white matter (WM) by measuring the diffusivity of water molecules. The dMRI signal, measured in Fourier space (i.e.  $\mathbf{q}$ -space), is related to the real Ensemble Average Propagator (EAP) through an inverse Fourier transform [1]. To efficiently describe the diffusion signal, analytical bases such as the 3D Simple Harmonic Oscillator based reconstruction and estimation (3D-SHORE) [2] and Mean Apparent Propagator MRI (MAP-MRI) [2] bases have been proposed. These bases capture the radial and angular properties of the dMRI signal by fitting a linear combination of orthogonal basis functions as  $E(\mathbf{q}) = \sum_i^N \mathbf{c}_i \Phi(\mathbf{q})$ . They then describe the EAP as  $P(\mathbf{r}) = \mathbf{c}_i \Psi(\mathbf{r})$  where  $\Psi(\mathbf{r})$  is the inverse Fourier transform of  $\Phi(\mathbf{q})$ . In this work we first bring to light and quantify an estimation bias wherein MAP-MRI consistently underestimates

fiber crossing angles. We then evaluate these bases both in terms of fiber crossing angle recovery using the Orientation Density Function (ODF) and microstructure recovery under clinically feasible setting.

## 2. MATERIALS AND METHODS

Both 3D-SHORE and MAP-MRI are based on the 1D-SHORE basis [3]. MAP-MRI only differs from 3D-SHORE by adapting the anisotropy of its basis functions to the anisotropy of the data, whereas 3D-SHORE uses isotropic basis functions. In fact, by setting MAP-MRI's basis function isotropic it is equivalent to 3D-SHORE [2]. Here we briefly outline the formulation of these bases and introduce a convenient way to relate the two.

### 2.1. MAP-MRI, 3D-SHORE and Scaling Anisotropy

The MAP-MRI basis functions are given as a product of three 1D-SHORE functions

$$\Phi_{N_i}(\mathbf{A}, \mathbf{q}) = \phi_{n_{x(i)}}(u_x, q_x) \phi_{n_{y(i)}}(u_y, q_y) \phi_{n_{z(i)}}(u_z, q_z) \quad (1)$$

with  $\begin{cases} \phi_n(u, q) = \frac{i^{-n}}{\sqrt{2^n n!}} e^{-2\pi^2 q^2 u^2} H_n(2\pi u q) \\ \mathbf{A} = \text{Diag}(u_x^2, u_y^2, u_z^2) \end{cases}$

with basis order  $N_i = (n_{x(i)}, n_{y(i)}, n_{z(i)})$  and  $H_n$  a Hermite polynomial. We find the diagonalized scaling factors  $\mathbf{A} = \mathbf{R} \mathbf{A}' \mathbf{R}^T$  by fitting a tensor  $\mathbf{A}'$  to the data, where  $\mathbf{R}$  contains the tensor eigenvectors. MAP-MRI rotates the data into the frame of reference using  $\mathbf{R}$  and scales the basis functions according to the diffusivity of tensor  $\mathbf{A}$  along each direction. The anisotropic scaling makes MAP-MRI quickly fit anisotropic data found in white matter tissue. Setting the scaling factors  $(u_x, u_y, u_z)$  to an isotropic  $u_0$  makes the MAP-MRI basis equivalent to the 3D-SHORE basis [2].

Using this relation we introduce a convenient way to scale the anisotropy of MAP-MRI's basis functions between isotropic 3D-SHORE and anisotropic MAP-MRI. We define the mixed scaling factors as

$$(u_x^{mix}, u_y^{mix}, u_z^{mix}) = u_0 + R_{\text{aniso}} * ((u_x, u_y, u_z) - u_0) \quad (2)$$

**Fig. 1:** ODFs of a noiseless multi-tensor crossing obtained using either MAP-MRI with basis order 6, 3D-SHORE with basis order 8 or CSD with spherical harmonics order 8 using only 60 samples. When a crossing is detected, the ground truth and the estimated fiber directions are shown as green and red lines. As you can see, MAP-MRI is able to resolve much smaller crossing angles than the other techniques, but also consistently underestimates the crossing angles smaller than 90 degrees.

where  $R_{\text{aniso}}$  scales the anisotropy. Setting  $R_{\text{aniso}} = 1$  or  $R_{\text{aniso}} = 0$  sets the fitting to either MAP-MRI or 3D-SHORE.

For arbitrary  $R_{\text{aniso}}$  we fit the basis coefficients  $\mathbf{c}$  to the data  $\mathbf{y} = E(\mathbf{q})$  using regularized least-squares as  $\mathbf{c} = \text{argmin}_{\mathbf{c}} \|\mathbf{y} - \mathbf{Q}\mathbf{c}\|^2 + \lambda R(\mathbf{c})$  where design matrix  $\mathbf{Q} \in \mathbb{R}^{N_{\text{data}} \times N_{\text{coef}}}$  has elements  $\mathbf{Q}_{ij} = \Phi_{N_i}(\mathbf{A}, \mathbf{q}_j)$ , with  $\mathbf{q}_j$  the  $q$ -space positions of the data. For  $R(\mathbf{c})$  we choose Laplacian regularization of the MAP-MRI basis [4] and use generalized cross-validation to find the regularization weight  $\lambda$  [5].

As the fitted basis coefficients linearly describe both the signal  $E(\mathbf{q})$  and the diffusion propagator  $P(\mathbf{r})$ , where  $\mathbf{r}$  defines the real displacement vector of a diffusing particle, they also linearly describe the Orientation Displacement (ODF) as

$$ODF_s(\mathbf{v}) = \int_0^\infty r^s P(r\mathbf{v}) dr = \sum_{i=0}^{N_{\text{max}}} \mathbf{c}_i \Omega_i(\mathbf{A}). \quad (3)$$

Here  $\mathbf{r} = \mathbf{v}r$  with  $\mathbf{v}$  an orientation on the unit sphere,  $s$  is the radial moment which induces a sharpening effect on the ODF ( $s = 2$  gives the marginal ODF), and  $\Omega$  is the ODF basis function. The closed form of  $\Omega$  can be found in [2]. Throughout this paper we use  $s = 6$  to retrieve ODF maxima.

## 2.2. Estimation of Scalar Quantities

From the fitted MAP-MRI coefficients we compute scalar indices known as the Return-to-Origin and Return-to-Axis Probabilities (RTOP and RTAP) [2]. In a given diffusion time, RTOP is defined as the probability that a spin does not have a net displacement (i.e.  $P(0)$ ) and RTAP as the integrated probability that a spin diffuses along the axis of the axons, here defined as the main tensor eigenvector  $\mathbf{R}_{\parallel}$ . When we represent axons are parallel cylinders we can relate RTAP to the mean cross-sectional area (MCSA) of the axons, from which we can then compute the mean axon radius [2].

However, this relation only holds if only the intra-axonal signal is considered, short gradient pulses are used ( $\delta \approx 0$ ) and long diffusion times are used ( $\Delta \gg \delta$ ) [6]. If these conditions are met we compute the axon radii as  $\langle R \rangle = \sqrt{1/(RTAP\pi)}$  with  $RTAP = \int_{\mathbb{R}} P(\mathbf{R}_{\parallel}r) dr$

## 3. RESULTS

Using synthetic data we investigate (I) the effect of MAP-MRI's anisotropic basis functions, (II) the angular recovery accuracy of 3D-SHORE, (III) the effect sampling data on multiple shells rather than a single shell and (IV) the effect truncating acquisitions on angle and axon radius recovery. We then use human data from the WU-Minn Human Connectome Project (HCP) [7] to investigate the effect truncating the data has on RTOP recovery.

### 3.1. Synthetic Results

In experiment (I) we generate fiber crossings with angles ranging from  $0^\circ$  to  $90^\circ$  using the multi-tensor model in Dipy [8]. The tensor eigenvalues are  $\{\lambda_x, \lambda_y, \lambda_z\} = \{1.7, 0.2, 0.2\} e - 3$ , and we sample 60 samples spread evenly over 3 shells at  $b = \{1000; 2000; 3000\}$  s/mm<sup>2</sup> [9]. In Fig. 1 we show ODFs computed using MAP-MRI, 3D-SHORE and as a reference Constrained Spherical Deconvolution (CSD) [10]. We observe that MAP-MRI is able to resolve smaller crossings but also consistently underestimates the crossing angle.

We quantify this effect using Eq. (2) to scale  $R_{\text{aniso}}$  between 0 (3D-SHORE) to 1 (MAP-MRI). Using a basis order of 8, we compute the mean squared signal reconstruction error (MSE) and estimate the crossing angle using the ODF on a  $45^\circ$ ,  $60^\circ$  and  $90^\circ$  fiber crossing. We observe that as  $R_{\text{aniso}}$  increases the MSE decreases (Fig. 2a) but the crossing underestimation increases (Fig. 2b), which corresponds with Fig.

**Fig. 2:** Synthetic experiment results. In (a) and (b) we investigate the effect of MAP-MRI’s basis anisotropy on signal reconstruction error and crossing angle recovery. In (c) we show the robustness of crossing angle recovery over the number of sampled gradient directions. In (d) and (e) we show the result of sampling on multiple shell on signal reconstruction and axon radius recovery. Finally (f) shows the robustness of axon radius recovery over the number of sampled gradient directions.

1. These results show that MAP-MRI is better suited for signal reconstruction and 3D-SHORE for angle recovery.

In experiment (II) we compare the angular accuracy of CSD and 3D-SHORE on tractography. We used the Tractometer evaluation system [11] on the synthetic ISBI 2013 reconstruction challenge data set [12] to compare tractography performances ( $SNR = 10, 20, 30$ ). Tractography was obtained for CSD (60 samples, one shell at  $b = 3000 \text{ s/mm}^2$ ) and 3D-SHORE (60 samples, spread evenly over 3 shells at  $b = \{1000; 2000; 3000\} \text{ s/mm}^2$ ) using the Dipy [8] EuDX deterministic tractography. EuDX tractography uses only the ODF maxima to propagate streamlines [8], and thus, is suitable to compare angular accuracy through tractography. We find that CSD and 3D-SHORE obtain similar results (Table not shown due to space limitations) on the Tractometer metrics [11], which is consistent with experiment (I).

We then study the effect of spreading the same number of samples over multiple sampling shells (III) using MAP-MRI. We use the cylinder model [3], which respects the conditions stated in Section 2.2, and sample 60 samples on either 1, 2 or 3 shells ( $b_{max} = 3000 \text{ s/mm}^2$ ) for different cylinder (axon) radii. We find that sampling over more shells decreases the MSE of the signal fitting (Fig. 2d) and allows for the recovery of smaller axon radii (Fig. 2e).

Finally in experiment (IV), we study how many samples we need to robustly recover crossing angles using 3D-SHORE

and recover axon radii using MAP-MRI. As in the Human Connectome Project data, for both we sample 270 samples over the same 3 b-shells and add noise 300 separate times such that  $SNR = 20$ . We then increasingly truncate the data, making sure the sampling distribution remains uniform [9], and compute the means and standard deviations of the recovered crossing angles (Fig. 2c) and axon radii (Fig. 2f). In Fig. 2c we see that all three crossings can be robustly estimated until we use less than 100 samples, at which point the smallest  $45^\circ$  crossing becomes difficult to recover. In Fig. 2f we see that MAP-MRI robustly recovers the chosen axon radii despite truncation to even 30 gradient directions.

### 3.2. Human Connectome Project: RTOP Recovery

We use the WU-Minn HCP data [7] to quantify the robustness of estimating RTOP using MAP-MRI on increasingly under-sampled data. The full HCP data has b-values  $\{0; 1,000; 2,000; 3,000\} \text{ mm}^2/\text{s}^2$  with  $\{18; 90; 90; 90\}$  gradient directions, ordered as in [9] such that subsets of the first  $N$  samples are still isotropic. We select a region of interest near the corpus callosum (Fig. 3) and compute RTOP using 270, 180, 90 and 60 samples. We see that RTOP’s white matter contrast is very similar even between 270 and 60 samples. We verify this by showing histograms of RTOP and the Kullback-Leibler divergence. Both confirm the similarity in RTOP values.

**Fig. 3:** Human Connectome Project (HCP) experiment results. We select a region of interest near the corpus callosum in the b0 image (left). Using MAP-MRI we compute RTOP in this area, where we increasingly truncate the data from the full 270 to just 60 gradient directions. Visually the RTOP value remain very similar despite truncation (middle). We verify their similarity with histograms of the RTOP values (top right) and by computing the Kullback-Leibler divergence (bottom right).

#### 4. DISCUSSION AND RESULTS

In this paper we showed that with just 60 sampled gradient directions, spread over 3 b-shells, we can accurately estimate both the directionality and microstructural measures of white matter tissue. We provided a way to scale the anisotropy of MAP-MRI's basis functions and quantified a consistent bias that MAP-MRI underestimates crossing angles under  $90^\circ$  as the anisotropy in its basis functions increases. Despite of this bias, we showed on both synthetic and human data from the Human Connectome Project that by using a mixed approach of 3D-SHORE for angle recovery and MAP-MRI for microstructure recovery we obtain the best results.

#### Acknowledgments

Data were provided [in part] by the Human Connectome Project, WU-Minn Consortium (Principal Investigators: David Van Essen and Kamil Ugurbil; 1U54MH091657) funded by the 16 NIH Institutes and Centers that support the NIH Blueprint for Neuroscience Research; and by the McDonnell Center for Systems Neuroscience at Washington University. This work was partly supported by the French ANR "MOSIFAH" under ANR-13-MONU-0009-01.
