Identification of long non-coding RNAs in insects genomes
Fabrice Legeai\textsuperscript{1,2} and Thomas Derrien\textsuperscript{3}

The development of high throughput sequencing technologies (HTS) has allowed researchers to better assess the complexity and diversity of the transcriptome. Among the many classes of non-coding RNAs (ncRNAs) identified the last decade, long non-coding RNAs (lncRNAs) represent a diverse and numerous repertoire of important ncRNAs, reinforcing the view that they are of central importance to the cell machinery in all branches of life. Although lncRNAs have been involved in essential biological processes such as imprinting, gene regulation or dosage compensation especially in mammals, the repertoire of lncRNAs is poorly characterized for many non-model organisms. In this review, we first focus on what is known about experimentally validated lncRNAs in insects and then review bioinformatic methods to annotate lncRNAs in the genomes of hexapods.

Introduction
Whole transcriptome sequencing experiments or RNAseq has become very popular as a means to monitor the population of RNAs in cells and to provide a unique snapshot of all transcripts present at a specific time-point in a particular cell type or tissue [1,2]. Beyond the classical messenger RNAs (mRNAs) that will be translated into proteins, RNAseq has shed light on the multiple classes of non-coding RNAs (ncRNAs) players pervasively transcribed from the genome. Recently, particular attention has been paid to the class of long non-coding RNAs (lncRNAs) since they have been connected to various mechanisms such as cis and/or trans regulation of transcription, dosage compensation, imprinting and competing endogenous RNA (see for recent reviews [3\textsuperscript{**},4\textsuperscript{***},5\textsuperscript{***},6\textsuperscript{***}]).

lncRNAs are arbitrarily defined as transcripts longer than 200 nucleotides that do not show any protein-coding capability and thus will not be translated into proteins [7]. Because of this vague definition, the catalog of lncRNAs represents a heterogeneous class of transcripts with mRNA-like characteristics, that is, transcribed by RNA polymerase II, 5' capped and often spliced [8].

Similar to the well-studied lncRNA XIST in mammals [9], pioneer work has been done in \textit{Drosophila melanogaster} through the identification of the ROX1/2 RNA genes involved in dosage compensation [10]. More recently, the modENCODE project annotated thousands of lncRNAs via a deep exploration of the fruitfly transcriptomes [11] reinforcing the view that ncRNAs are essential components to link genotype to phenotype relationships. However, while the repertoire of annotated lncRNAs is regularly improved in phylogenetically distant species [12], many non-model organisms still do not benefit from the annotation of these functional elements of the genomes [13\textsuperscript{*}]. In this review, we first compiled available biological information on functionally validated lncRNAs in insect genomes with particular emphasis on lncRNAs in fruitfly and honeybee species and then discussed the method to annotate lncRNAs using RNAseq.

Resources and known functions for lncRNAs in insects
At least 72 active databases are dedicated to collecting biological information about ncRNAs [14] including LNCipedia [15] and lncRNome [16], which are specifically devoted to catalog lncRNAs and describe their functions based on literature. Even if most of them are still limited to human or mouse organisms, more generalist databases such as NonCode [17] aim at gathering all ncRNA sequences produced from experimental protocols or derived from automatic computational scans, with emphasis on a dozen of model organisms, including \textit{Drosophila melanogaster}. While the fourth version of NonCode contains more than 200 thousands human and mouse lncRNAs, it registers only 3193 lncRNAs from fruitfly, all of them being automatically predicted from RNAseq data (see below) without further functional description. On the other hand, the RNA family database

www.sciencedirect.com
RFam [18] and lncRNAdb [19], databases, both accessible through the RNACentral repository [20*], comprise a set of experimentally verified ncRNAs which are also searched in other organisms using both sequence and structural similarity strategies. Interestingly, while RNACentral stores a total of 40,182 lncRNAs only a few concern insect models.

Among them, much attention has been focused on two particular insect species: fruitfly and honeybee. The first because it benefits from outstanding resources for experimental investigation and validations, and the second because of its particular social behaviors and caste polyphenism, the latter processes mainly involve epigenetics [21**]. In Table 1, we briefly describe the few well-studied long ncRNAs for which functions have been characterized to date in fruitfly and honeybee. We show that these lncRNAs could be broadly classified into main biological mechanisms such as development (lncRNA bithorax), behavior (sphinx and NB-1) or neural

**Development**

| bithorax | Drosophila melanogaster | The bithorax complex (BX-C) plays a key role in Drosophila development and covers a region larger than 300 kb that includes only four protein-coding genes. Non-coding genes have already been shown to be concomitantly expressed from the BX-C domain to regulate in cis the BX-C proteins in specific abdominal segments [26,27] | Cis |

| Lnccov1/2 | Apis mellifera | These two transcripts lack evidence of functional ORFs and are differentially expressed in queen and worker ovariole transcriptomes at the embryonic stage. Temporal expression shows that lnccov1 might be involved in the autophagic cell death of ovarioles during worker embryogenesis, and fluorescent in situ hybridization (FISH) indicates perinuclear localization in omega speckle-like structures [28] | Unknown |

**Behavior**

| yar | Drosophila melanogaster | yar is a long non-coding RNA, highly expressed during embryogenesis and located in a neural gene cluster between yellow (y) and achaete (ac) [29]. With the help of mutants, the function of this long non-coding RNA has been recently refined as a regulator of y and ac transcription, affecting as well the sleep behavior of the Drosophila [30] | Cis |

| sphinx | Drosophila melanogaster | sphinx is a lncRNA involved in the regulation of male courtship behavior. Sequence variations between close Drosophila species advocate for a functional role and a rapid adaptation. The mutagenesis of sphinx in Drosophila reveals the emergence of male-male courtship behavior, probably by the disruption of some sensory circuits, which is supported by its specific expression in chemosensory organs [31] | Unknown |

| Nb-1 | Apis mellifera | Nb-1 is a 700 nt transcript, whose longest ORF encodes a putative 32 amino acid without any sequence conservation. This lncRNA is expressed in the honeybee brain with variation according to the age of the colony workers testifying to its putative role in polyethism [32] | Unknown |

**Neural expression**

| Ks-1 | Apis mellifera | Sawata et al. identified a 17knt transcript that is expressed restrictively in the mushroom body of Kenyon cells in the honeybee brain and which accumulates in the nucleus. The transcript exhibits seven putative ORFs longer than 67 amino acids without any conservation in a related species (Apis cerana) nor similarity with known proteins [33] | Unknown |

| AncR-1 | Apis mellifera | AncR-1 is preferentially expressed in the brain, in sexual tissues and in some secretory organs and accumulates in nuclei. It contains multiple alternate isoforms, which are derived from a 6.9 kbp genomic locus [34] | Unknown |

| Kakusei | Apis mellifera | The kakusei is a ~7000 nt long non-coding RNA with multiple constitutive and inducible variants, the expression of which is transiently up-regulated by neural activity. It is localized exclusively in neural nuclei in discrete nuclear compartments. This gene may play specific roles in RNA metabolism in the honeybee brains, irrespective of behavioral experience [35] | Unknown |
expression (kakusei). In these species, the mode of action of the lncRNAs involves either broad trans-regulation by epigenetic control of chromatin (re)organization or RNA sequestration in a nuclear compartment (such as omega-speckles), as well as neighboring cis-regulation of specific mRNA genes, both during development or following a stress.

In other insect model organisms, such as *Acrithosiphon pisum, Aedes gambiae, Anopheles gambiae, Danaus plexippus* or *Heliconius melpomene* no in-depth functional analysis of putative lncRNA have been published to date. But, interestingly, in the red flour beetle *Tribolium castaneum*, numerous ncRNAs are expressed on the opposite strand of protein-coding genes localized in the Hox cluster [36]. Similarly, Li et al. recently observed that some ncRNAs of intermediate sizes are transcribed from the silk gland of *Bombyx mori* and may be involved in the repression of transcription by epigenetic modifications of histones [37]. Finally, in *Nasonia vitripennis*, where some individuals contain a paternally transmitted supernumerary chromosome (Paternal Sex Ratio, PSR), the paternal chromatin is modified during the first mitotic division via retention of histone H3 in a phosphorylated state. This first exhaustive transcriptome study in testis tissue revealed the presence of four putative ncRNAs that are specific to individuals having a PSR [38].

In contrast to short ncRNAs such as tRNAs or miRNAs, neither the sequence nor the structure of the lncRNA appear to be phylogenetically conserved throughout the metazoa kingdom [39] or even among the insects even when the biological processes involving lncRNA functions are similar between species. As a result, new specialized computational prediction protocols and tools are being developed to discriminate coding versus non-coding transcripts and to refine the functional annotation of lncRNAs (see next section for details). Thanks to the recent advances in sequencing technologies (RNA-Seq), the systematic identification of long ncRNAs has already been applied to few insects having high-quality genome assemblies in order to complete the repertoire of functional elements in their genomes (Table 2).

### Bioinformatics workflows for the systematic identification and annotation of lncRNAs

In order to annotate lncRNAs, a typical workflow (Figure 1) could be applied to the growing number of assembled insect genomes with particular attention on the following three key points.

### RNASeq protocols
Whole transcriptome sequencing (RNASeq) represents the method of choice to discover new transcripts and also to quantify all RNAs in a variety of organisms, cell types
or tissues [1]. Even if RNASeq technology has become the ‘de facto’ standard for transcriptome profiling, it is worth noting that this technology undergoes rapid evolution in terms of library preparation, sequencing platforms and subsequent bioinformatics analyses leading to regular updates of guidelines and standards [45].
Given that first, IncRNAs tend to be rare compared to mRNAs and second, display both spatial and temporal expression patterns [8], the depth of sequencing, the number of different tissues/cell lines and time-points need to be considered in planning each experiment. For instance, it has been shown in human and fruitfly that testis tissue shows the highest number of tissue-specific IncRNAs (e.g. 11% of all IncRNAs in Drosophila) probably reflecting more relaxed chromatin structure [11]. In addition, many IncRNAs, are expressed antisense to protein-coding genes [46,47], which they often regulate [48]. It is thus recommended to favor stranded RNASeq protocols (also known as directional transcriptome sequencing) that keep track of the strand of origin of the transcript [49] if the purpose of the study includes the identification of antisense IncRNAs. For example, using these stranded protocols, the modENCODE project recently discovered 402 IncRNA loci (21% of all IncRNA loci) located antisense to mRNA transcripts of protein coding genes in D. melanogaster [11] while this proportion is slightly lower (~15%) in the human genome [8].

**Mapping and reconstructing IncRNAs**

When a high quality reference genome is available, one would favor a map-first then assembly strategy. To this end, the common but still critical point in RNASeq analysis consists of mapping the millions of sequenced reads onto a reference genome. Fortunately, several software solutions or mappers have been developed in the last few years that efficiently and rapidly align reads on a reference genome [50–53]. Regarding RNASeq reads, the task is even more challenging since the mapper should also handle spliced-read alignments, that is, reads mapping over exon/intron junctions (see for benchmark [54]). Since many of the IncRNAs are multiexonic, the use of spliced-read aligners is critical to precisely discover novel exon junctions as for IncRNAs. In D. melanogaster, Young et al. used a more stringent mapping protocol by forcing read mapping onto exon junctions connecting mRNAs ends and known adjacent intergenic transcripts [42**] in order to exclude possible false positive intergenic IncRNAs [55]. The resulting mapping file is then used by graph-based approaches such as cufflinks [56], scripture [57] or FluxSimulator [58] to reconstruct all transcript models. Despite intensive works in this area, these methods are far from being perfect in terms of accuracy, sensitivity and specificity but seem to behave better for smaller genomes (nematode and fruitfly) compared to mammalian genomes [59].

**Measuring the coding potential**

Once a set of transcripts has been assembled, it is important to estimate the protein-coding potential of the sequences. After having removed transcripts whose size is below a certain cutoff (often 200 nt for IncRNA), a first step could be the filtering of transcripts which overlap mRNAs exons in the sense orientation as they more likely correspond to novel isoforms of a protein-coding gene. Subsequently, two kinds of methods are available to classify coding versus non-coding transcripts using computational programs and/or biochemical experiments. Computationally, the coding potential could be determined by measuring the intrinsic properties of the sequences which correspond (non-exhaustively) to first, the length of the Open Reading Frame (ORF), second, the coverage of the ORF compared to the length of the transcripts, third, the bias in k-mer frequencies between coding and non-coding sequences and fourth, the presence of protein-coding specific motifs [60,61]. All these features are often integrated into machine learning algorithms such as a support vector machine (SVM) or random forest (RF), which are trained with known sets of protein-coding and non-coding transcripts. Additionally, some other tools also require the alignment of the candidate IncRNAs sequences with protein databases (such as PFAM or Swiss-Prot) to search for evidence of translatability [62] or with multiple genomes in order to specifically tag the selective pressure acting on mRNAs [63]. However, the former method suffers from the inherent lack of protein sequences (especially for insect proteomes) and may therefore lead to false positive annotation of insect IncRNAs while the latter implies that IncRNAs are evolutionary conserved which may not be the case with respect to both the phylogenetic distances [39] and effective population sizes [64**]. Finally, further work is needed to develop programs that simulate non-coding sequences in the absence of non-coding training sets.

At the experimental level, evidence for protein-coding capability can be directly obtained by mass spectrometry data [65] although these experiments may not be available for all insect species. Another complementary technique, ribosome profiling, was developed by Ingolia et al. and utilizes high throughput sequencing to map RNA regions associated with translating ribosomes [66]. While some IncRNAs have been shown to be associated with ribosomes suggesting that they are in fact wrongly annotated, it is still unclear whether the resulting short peptides are really functional since they are also reported in the 5’UTR of protein-coding transcripts.

**Conclusion and future directions**

Despite growing evidence that IncRNAs are key players in mammalian cells, only a few of them have been experimentally validated in insects, mostly in D. melanogaster. As a proof of concept for IncRNA functionality, the well-studied RNArox genes are involved in dosage compensation similar to the Xist gene in mammals [9].

Many new insect IncRNAs will be discovered in the next few years owing to both the availability of cheaper RNASeq protocols and the development of dedicated bioinformatics programs. For instance, when a reference genome is not available or when the quality of the genome assembly is relatively poor (which may be the
Insect genomics

case for several non-model organisms), de novo or genome-independent assembly approaches [67–69] have to be envisaged to better identify the lncRNAs repertoire.

Moreover, differentiating non-coding from coding transcripts remains a challenging task [70] and can be hampered by biological artifacts. Indeed, at least two *Drosophila* lncRNAs (preg and polished rice) have been recently re-classified as coding for small peptides [71,72]. Furthermore, bioinformatics tools are still missing that distinguish bifunctional RNAs such as the steroid receptor activator gene (SRA) [73] harboring two different functions, one at the RNA level and another when translated into proteins.

Finally, it is obvious that new experimental methods have to be implemented to understand the function of these intriguing RNAs, such as the recent and promising technologies CHART [74] or dChIRP [75*], that can be applied to identify the DNA binding sites of lncRNAs. In parallel, computational approaches are required to unveil functions of lncRNAs on a large-scale perspective. As illustrated by the recent implementation of lncRNAtoR [76*], a new database integrating functional information about lncRNAs from six species, including fruitfly. These attempts have to be extended to non-model organisms in order to shed light on the many components of the genome (coding and non-coding) that are responsible for phenotypic traits.
