Abstract

This article is on message-passing systems where communication is (a) synchronous and (b) based on the “broadcast/receive” pair of communication operations. “Synchronous” means that time is discrete and appears as a sequence of time slots (or rounds) such that each message is received in the very same round in which it is sent. “Broadcast/receive” means that during a round a process can either broadcast a message to its neighbors or receive a message from one of them. In such a communication model, no two neighbors of the same process, nor a process and any of its neighbors, must be allowed to broadcast during the same time slot (thereby preventing message collisions in the first case, and message conflicts in the second case). From a graph theory point of view, the allocation of slots to processes is known as the distance-2 coloring problem: a color must be associated with each process (defining the time slots in which it will be allowed to broadcast) in such a way that any two processes at distance at most 2 obtain different colors, while the total number of colors is “as small as possible”.

The paper presents a parallel message-passing distance-2 coloring algorithm suited to trees, whose roots are dynamically defined. This algorithm, which is itself collision-free and conflict-free, uses \(\Delta + 1\) colors where \(\Delta\) is the maximal degree of the graph (hence the algorithm is color-optimal). It does not require all processes to have different initial identities, and its time complexity is \(O(d\Delta)\), where \(d\) is the depth of the tree. As far as we know, this is the first distributed distance-2 coloring algorithm designed for the broadcast/receive round-based communication model, which owns all the previous properties.

Keywords: Broadcast/receive communication, Collision, Conflict, Distance-2 graph coloring, Message-passing, Network traversal, Synchronous system, Time slot assignment, Tree network, Wireless network.
1 Introduction

Graph coloring is an important problem related to (optimal) resource allocation, mainly used to establish an optimal order in which resources have to be allocated to processes [13, 24]. The distance-$k$ coloring problem consists in assigning colors to the vertices of the graph such that no two vertices at distance at most $k$ have the same color. Let us remember that minimum distance-$1$ vertex coloring is an NP-complete problem [16].

Coloring is (with leader election [1] and renaming [2, 10]) one of the most important symmetry breaking problems encountered in distributed computing [20]. Solving such problems requires a pre-existing initial asymmetry from which the problem can be solved. In a lot of cases, this initial asymmetry is given by the assumption that no two processes have the same identity.\footnote{Let us notice that one of the oldest symmetry-breaking problems is mutual exclusion, where the problem has not to be solved once for all, but repeatedly in a fair way [29]. See also the monograph [3] for impossibility results in distributed computing due to symmetry/indistinguishability arguments.}

**Distributed distance-1 coloring in the classical point-to-point synchronous message-passing model**

Let us consider a distributed computing setting, where the processes constitute the vertices of a graph, and the communication channels its edges. The distributed distance-1 vertex coloring problem consists in associating a color with each process such that (a) no two neighbors have the same color, and (b) the total number of colors is as small as possible. This process-coloring problem has essentially been investigated in reliable synchronous networks where any two neighboring processes are connected by a bi-directional channel on which each of them can send and receive messages (e.g. [26, 30, 31, 32]). The main results are described in the monograph [5].

In these reliable point-to-point synchronous systems, processes proceed in synchronized steps, usually called rounds. Each round consists of three phases: during the first phase, each process sends messages to its neighbors; during the second phase, each process receives messages; and during the last phase, each process executes local computation. The fundamental synchrony property is that a message is received in the very same round in which it is sent. Hence, when solving a problem in this synchronous computation model, a crucial attribute of a problem is the minimal number or rounds needed to solve it. As far as the distance-1 coloring problem is concerned, it has been shown that, if the communication graph can be logically oriented such that each process has only one predecessor (e.g., a tree or a ring), $O(\log^* n)$ rounds are necessary and sufficient to color the processes with three colors [12, 23] ($n$ being the total number of processes\footnote{$\log^* n$ is the number of times the function $\log$ needs to be iteratively applied in $\log(\log(\log(\cdots(\log n))))$ to obtain a value $\leq 2$. As an example, if $n$ is the number of atoms in the universe, $\log^* n \simeq 5$.}). Other $d_1$-coloring algorithms are described in several articles (e.g. [4, 6, 18, 22]). They differ in the number of rounds they need and in the number of colors they use to implement $d_1$-coloring. Both the algorithms in [4, 6] color the vertices with $(\Delta + 1)$ colors; the first one requires $O(\Delta + \log^* n)$ rounds, while the second one uses $O(\log \Delta)$ rounds. An algorithm described in [18] is for tree graphs or graphs where each vertex has two neighbors; it uses three colors and $O(\log^* n)$ rounds. Another algorithm presented in the same paper addresses constant-degree graphs; it uses $(\Delta + 1)$ colors and $O(\log^* n)$ rounds. The algorithm presented in [22] requires $O(\Delta \log \Delta + \log^* n)$ rounds. These algorithms assume that the processes (vertices) have distinct identities, which are their initial colors. They proceed iteratively, each round reducing the total number of colors.

**Distance-2 and distance-3 coloring in shared memory and message-passing models**

A first class of algorithms addresses the distance-2 vertex coloring problems in systems where communication is through
shared memory, message-passing, or a mix of the two [8, 9, 17]. These algorithms find their motivation in the application of distance-2 coloring to scientific computing. As a result, they do not fit well the characteristics of wireless networks.

On the other hand, wireless protocols apply or require distance-2 and distance-3 coloring algorithms to prevent packet collisions [11]. To this end, they build a TDMA (Time Division Multiple Access) schedule [28] from the result of the coloring process. TDMA allows processes to share the same frequency channel by dividing the signal into different time slots, one per color. Hence, protocols based on distance-2 coloring guarantee that nodes can transmit messages undisturbed during their time slots. Those based on distance-3 coloring additionally allow receiving nodes to acknowledge unicast messages in the sender’s slot.

With this motivation, some authors have proposed self-stabilizing algorithms to solve the distance-2 problem [7, 15] For example, [7] presents a self-stabilizing distance-2 algorithm that uses a constant number of variables on each node and that stabilizes in $O(\Delta^2 m)$ moves and uses at most $\Delta^2$ colors, where $m$ is the number of edges. But these algorithms do not take the broadcast nature of the wireless medium into account, and their operation may thus result in significant packet collisions.

Differently, CADCA [21] is a distributed distance-2 coloring algorithm that takes into account the risk of collisions during the coloring process. To limit this risk, CADCA organizes the nodes to be colored in concentric layers around a sink node. The coloring process proceeds in three phases: the first colors layers 1, 4, 7, ..., the second colors layers 2, 5, 8, ..., and the third colors layers 3, 6, 9. Each such phase uses a specific color palette to avoid conflicts between nodes in different layers and exploits five stages in which the nodes in a layer select colors and resolve the conflicts that arise during the process. However, the algorithm requires nodes to know their position with respect to the sink node, and most importantly it does not entirely eliminate packet collisions, it only reduces their number.

With respect to the distance-3 version of a problem, [19] proposes a self-stabilizing algorithm. Processes compute a maximal independent set and then use it to assign themselves colors. The self-stabilizing part of the algorithm gathers information about each process’s 3-hop neighborhood, and does generate collisions. However, the protocol uses a special TDMA slot to continuously run the self-stabilizing protocol without interfering with colored slots. Serena [25] uses a similar approach and also presents a distance-3 coloring algorithm in a broadcast-receive model. However, it does not use a special time-slot to limit the impact of the collisions occurring during the coloring process. The protocols we present in this paper, on the other hand, do not lead to any conflict or collision and do not need any special time slots.

Content of the paper  Differently from the previous articles, we propose a collision- and conflict-free algorithm that solves the distance-2 ($d_2$) coloring problem in synchronous networks where (a) processes communicate by broadcasting and receiving messages, and (b) collisions and conflicts are not prevented by the communication model. A collision occurs when a process receives messages from two or more neighbors in the same round. A conflict occurs when, during the same round, two neighbors send a message to each other.

In this broadcast/receive communication model (which covers practical system deployments), there is not a dedicated communication medium for each pair of processes, but a single shared communication medium for each pair composed of a process and all its neighbors. Examples of such communication media are encountered in wireless networks such as sensor networks. In such networks, collision-freedom and conflict-freedom do not come for free, and the algorithms built on top of them must be collision/conflict-free to ensure the consistency of the messages that are exchanged, and consequently the progress of upper-layer applications.

This paper is on collision/conflict-free $d_2$-coloring for the synchronous broadcast/receive communica-
tion model, where the processes are connected by a tree network. Considering such a context, it presents an algorithm which uses $(\Delta + 1)$ colors, and is consequently optimal with respect to the number of colors. This algorithm relies on two assumptions to break symmetry: (a) it assumes that a process (not predetermined in advance) receives an external message that defines it as the root of the tree; (b) it assumes that any two processes at distance less than or equal to 2 have distinct identities (hence, depending on the structure of the tree, lots of processes can have the same identity). Its round complexity is $O(d\Delta)$ where $d$ is the depth of the tree. Moreover, no process needs to know $n$, $\Delta$, or the depth of the tree. Hence a process has no information on the global structure of the tree. Its initial knowledge is purely local: it is restricted to its identity, and the identities of its neighbors.

**Roadmap** The paper consists of 6 sections. Section 2 presents the synchronous broadcast/receive model, and Section 3 introduces the distance-2 coloring problem. Then, two distributed (message-passing) distance-2 coloring algorithms suited to trees are presented. The presentation is incremental. Section 4 presents first a simple distributed distance-2 coloring algorithm which exploits a sequential tree traversal algorithm as a skeleton, on which are appropriately grafted statements implementing distance-2 the coloring. Then, Section 5 presents a distributed distance-2 coloring algorithm based on a parallel traversal of the tree. This second algorithm extends the basic coloring principles introduced in the first algorithm.

## 2 Synchronous Broadcast/Receive Model

**Processes, initial knowledge, and the communication graph** The system model consists of $n$ sequential processes denoted $p_1, ..., p_n$, connected by a tree communication network.

Each process $p_i$ has an identity $id_i$, which is known only by itself and its neighbors (processes at distance 1 from it). The constant $neighbors_i$ is a local set, known only by $p_i$, including the identities of its neighbors (and only them). As noticed in the Introduction, in order for a process $p_i$ not to confuse its neighbors, it is assumed that no two processes at distance less than or equal to 2 have distinct identities. Hence, any two processes at distance greater than 2 may have the same identity. When computing bit complexities, we will assume that any process identity is encoded in $\log_2 n$ bits.

Let $\Delta_i$ denote the degree of a process $p_i$ (i.e. $|neighbors_i|$) and let $\Delta$ denote the maximal degree of the process graph ($\max\{\Delta_1, \cdot \cdot \cdot, \Delta_n\}$). While each process $p_i$ knows $\Delta_i$, no process knows $\Delta$ (a process $p_x$ such that $\Delta_x = \Delta$ does not know that $\Delta_x$ is $\Delta$).

When considering a process $p_i$, $1 \leq i \leq n$, the integer $i$ is called its index. Indexes are not known by the processes. They are only a notation convenience used as a subscript to distinguish processes and their local variables.

**Timing model** We assume that processing durations are equal to 0. This is justified by the following observations: (a) the duration of the local computations of a process is negligible with respect to message transfer delays, and (b) the processing duration of a message may be considered as a part of its transfer delay.

Communication is synchronous in the sense that there is an upper bound $D$ on message transfer delays, and this bound is known by all the processes (global knowledge). From an algorithm design point of view, we consider that there is a global clock, denoted $CLOCK$, which is increased by 1, after each period of $D$ physical time units. Each value of $CLOCK$ defines what is usually called a time slot or a round.

---

1Let us notice that this assumption states nothing more than the fact that a process is able to distinguish its neighbors based on their identities.
Communication operations The processes are provided with two operations denoted broadcast() and receive(). A process \( p_i \) invokes broadcast \( \text{TAG}(m) \) to send the message \( m \), whose type is \( \text{TAG} \), to all its neighbors. It is assumed that a process invokes broadcast() only at a beginning of a time slot. When a message \( \text{TAG}(m) \) arrives at a process \( p_i \), this process is immediately warned of it, which triggers the execution of operation receive() to obtain the message. Hence, a message is always received and processed during the time slot –round– in which it was broadcast.

From a linguistic point of view, we use the two following when notations when writing algorithms, where predicate is a predicate involving \( \text{CLOCK} \) and possibly local variables of the concerned process.

- **when \( \text{TAG}(m) \) is received do** processing of the message.
- **when predicate do** code entailing at most one broadcast() invocation.

Message collision and message conflict Traditional wired round-based synchronous systems assume a dedicated a communication medium for each pair of processes (i.e., this medium is not accessible to the other processes). Hence, in these systems a process \( p_i \) obeys the following sequential pattern during each round: (a) first \( p_i \) sends a message to all or a subset of its neighbors, (b) then \( p_i \) receives the messages sent to it by its neighbors during the current round, and (c) finally executes a local computation which depends on its local state at the beginning of the round and the messages it has received during the current round.

The situation is different in systems such as wireless networks (e.g., sensor networks), which lack a dedicated communication medium per pair of processes. A process \( p_i \) shares a single communication medium with all its neighbors, and “message clash” problems can occur, each message corrupting the other ones, and being corrupted by them. Consider a process \( p_i \), these problems are the following.

- If two neighbors of \( p_i \) invoke the operation broadcast() during the same time slot (round), a message collision occurs.
- If \( p_i \) and one of its neighbors invoke broadcast() during the same time slot (round), a message conflict occurs.

As already indicated, this paper considers this broadcast/receive communication model. This implies that protocols must prevent collisions and conflicts to ensure both message consistency and computation progress.

### 3 The Distance-2 Tree Coloring Problem

Solving the collision/conflict problem To prevent collisions and conflicts involving a process \( p_i \), only a single process in the set \( \{ p_i \} \cup \text{neighbors} \) can obtain the right to communicate during a given round. To this end, we associate each process with time slots (rounds) in which it can broadcast a message, while none of its 2-hop neighbors can broadcast during these time slots. When considering the whole set of processes, this assignment must be optimal in terms of numbers of colors (ideally allowing as many processes as possible to broadcast during the same round).

This problem is a well-known graph coloring problem called distance-2 coloring. The aim is to design distributed algorithms associating a color with each process (which will define the time-slots during which it will be allowed to broadcast) such that the following properties are satisfied.

**Definition**

- **Validity**: The final color of each process belongs to \( \{0, \ldots, \Delta\} \).
- **Consistency**: No two processes at distance \( \leq 2 \) have the same color.
Termination: Each process obtains a color and one process knows that this occurred.

Let us observe that, as at least one process has $\Delta$ neighbors, $\Delta + 1$ different colors are necessary. The Validity property states that we are looking for distributed algorithms which ensure that $\Delta + 1$ is also a tight upper bound. As we will see such algorithms exist for tree networks.

Using the colors to define the time slots The colors obtained by the processes are used as follows, where $\text{color}_i$ is the color obtained by process $p_i$. The time slots (rounds) during which $p_i$ is allowed to broadcast a message to its neighbors correspond to the values of $\text{CLOCK}$ such that $((\text{CLOCK} \mod (\Delta + 1)) = \text{color}_i)$. As we will see, these time slots are different from the time slots used during the (sequential and parallel) distributed distance-2 algorithms which are presented below. It follows that these algorithms must provide each process with the (initially unknown) value of $\Delta$.

4 Sequential Distance-2 Coloring of a Tree

This section presents a distributed distance-2 coloring algorithm in which there are neither message collisions, nor message conflicts. This algorithm is sequential in the sense that its skeleton is a depth-first tree traversal in which the control flow (implemented by appropriate messages) moves sequentially from a process to another one.

4.1 A sequential algorithm

Algorithm 1 assumes that a single process receives a message, $\text{START()}$, which defines it as the root of the tree. (As noticed in the Introduction, this introduces the initial asymmetry needed to solve the symmetry-breaking problem we are interested in.) This external message causes the receiving process, $p_r$, to simulate the reception of a fictitious message, $\text{COLOR}(\text{id}_r, \text{id}_r, -1, \emptyset)$. This message initiates a depth-first traversal of the tree.

Messages The algorithm uses two types of messages: $\text{COLOR()}$ and $\text{TERM()}$. As each message is broadcast by its sender and received by all its neighbors, it carries the identity of its destination process. Hence, when a process receives a message $m$, it discards $m$ if it is not the destination of $m$ (predicate $\text{dest} \neq \text{id}_i$ at line 04 and line 19).

These messages implement a depth-first traversal of the tree network [31]. Each carries the identity of its destination ($\text{dest}$), the identity of its sender ($\text{sender}$), and the color of its sender ($\text{sender}_\text{cl}$). A message $\text{COLOR()}$ additionally carries the colors of the already colored neighbors of the sender ($\text{colors}$).

Local variables Each process $p_i$ manages the following local variables.

- $\text{state}_i$ (initialized to 0) is used by $p_i$ to manage the progress of the tree traversal. Each process traverses five different states during the execution of the algorithm. States 1 and 3 are active: a process in state 1 sends a $\text{COLOR()}$ message to a child, while a process in state 3 sends a $\text{TERM()}$ message to its parent. States 0 and 2 are waiting states. Nodes listen on the broadcast channel but cannot send any message. Finally, state 4 identifies local termination.
- $\text{parent}_i$ saves the identity of the process $p_j$ from which $p_i$ received the message $\text{COLOR(id}_i, -, -, -)$; $p_i$ receives exactly one such message. This process, $p_j$, defines the parent of $p_i$ in the tree. The root
$p_r$ of the tree, defined by the reception of the external message $\text{START}()$, is the only process such that $\text{parent}_r = \text{id}_r$.

- $\text{sender}_i$ records the color of the parent of $p_i$. $p_i$ receives this information in the parent’s COLOR message.
- $d1\text{colors}_i$ is a set containing the colors of the neighbors of $p_i$, that have already obtained their color.
- $\text{to\_color}_i$ (initialized to $\text{neighbors}_i$) is a set containing the identities of the neighbors of $p_i$ not yet colored.
- $\text{color}_i$ contains the color of $p_i$.

**Initialization:** $\text{state}_i \leftarrow 0$; $\text{to\_color}_i \leftarrow \text{neighbors}_i$.

(01) **when $\text{START}()$ is received** do % a single process $p_i$ receives this external message %
(02) $p_i$ executes the lines 04-09 as if it received the message $\text{COLOR}(\text{id}_i, \text{id}_i, -1, \emptyset)$.

(03) **when $\text{COLOR}(\text{dest}, \text{sender}, \text{sender}_i, d1\text{colors})$ is received** do
(04) if $(\text{dest} \neq \text{id}_i)$ then discard the message (do not execute lines 05-09) end if;
(05) $\text{parent}_i \leftarrow \text{sender}_i$; $\text{sender}_i \leftarrow \text{sender}_i$; $d1\text{colors}_i \leftarrow \text{sender}_i$;
(06) $\text{palette} \leftarrow$ sequence 0, 1, 2, ... without the colors in $\{\text{sender}_i\} \cup d1\text{colors}$;
(07) $\text{color}_i \leftarrow$ first color in $\text{palette}$;
(08) $\text{to\_color}_i \leftarrow \text{neighbors}_i \setminus \{\text{parent}_i\}$;
(09) if $(\text{to\_color}_i \neq \emptyset)$ then $\text{state}_i \leftarrow 1$ else $\text{state}_i \leftarrow 3$ end if.

(10) **when $(\text{CLOCK increases}) \land (\text{state}_i \in \{1, 3\})$ do
(11) if $(\text{state}_i = 1)$
(12) $\text{next} \leftarrow$ any $\text{id}_k \in \text{to\_color}_i$;
(13) broadcast $\text{COLOR}(\text{next}, \text{id}_i, \text{color}_i, d1\text{colors}_i)$; $\text{state}_i \leftarrow 2$
(14) else if $(\text{parent}_i = \text{id}_i)$ then the root $p_i$ claims termination
(15) else broadcast $\text{TERM}(\text{parent}_i, \text{id}_i, \text{color}_i)$
(16) end if;
(17) $\text{state}_i \leftarrow 4$

(18) **when $\text{TERM}(\text{dest}, \text{id}, \text{sender}_i)$ is received** do
% the tree rooted at process $id$ is properly colored %
(19) if $(\text{dest} \neq \text{id}_i)$ then discard the message (do not execute lines 20-21) end if;
(20) $\text{to\_color}_i \leftarrow \text{to\_color}_i \setminus \{\text{id}\}$; $d1\text{colors}_i \leftarrow d1\text{colors}_i \cup \{\text{sender}_i\}$;
(21) if $(\text{to\_color}_i \neq \emptyset)$ then $\text{state}_i \leftarrow 1$ else $\text{state}_i \leftarrow 3$ end if.

Algorithm 1: Distributed depth-first-based distance-2 coloring of a tree (code for $p_i$)

**Description of the algorithm**  Nodes start the algorithm in state 0, waiting for a $\text{COLOR}(\text{id}_i, -, -, -)$ message. A process, $p_i$, receives such a message exactly once. When it receives it, it is visited for the first time by the depth-first tree traversal. It consequently assigns the values of the message parameters to its local variables $\text{parent}_i$, $\text{sender}_i$ and $d1\text{colors}_i$ (line 05). Then, it computes its color, which is different from the color of the sender of the message and from the colors of the sender’s already colored neighbors (lines 06-07). Finally, $p_i$ updates $\text{to\_color}_i$, and transitions to a new state: 1 if it has any children, or 3 if it is a leaf node. This prepares the progress of the tree traversal, which will take place at the next time slot (round) (lines 08-09).

When $p_i$ enters the new time slot with $\text{state}_i \in \{1, 3\}$ (line 10), it operates as follows to ensure the progress of the tree traversal.
• If $state_i = 1$, it means that $p_i$ has neighbors that have not yet been colored. In this case, $p_i$ selects one of them, and makes the tree traversal progress by broadcasting a message, $COLOR(next, id_i, color_i, d1colors_i)$, which will be processed only by $next$ (line 13). Then, $p_i$ moves into $state_i = 2$ and waits until it receives a $TERM$ message, $TERM(id_i, next, -)$.

• If $state_i = 3$, it means that all the neighbors of $p_i$ have been colored. In this case, if $p_i$ is the root, the distance-2 coloring has terminated (line 14). Otherwise, if $p_i$ is not the root, it broadcasts the message $TERM(parent_i, id_i, color_i)$ to inform its parent that the sub-tree of which it is the root has been colored (line 15). In both cases, $p_i$ transitions to $state_i = 4$, thereby indicating that the algorithm is terminated as far as $p_i$ is concerned (local termination).

Finally, when $p_i$ receives the message $TERM(id_i, id, sender_i, cl)$, it first updates its local variables $to\_color_i$ and $d1colors_i$ according to the received values (line 20). Then, it updates $state_i$ according to the value of $to\_color_i$ (indicating whether it has colored all its neighbors, line 21). In the first case, it moves to state 1 and continues traversing another sub-tree. Otherwise it moves to state 3, which will then evolve into state 4 (signaling local termination) as indicated above.

**How a process learns the value of $\Delta$** A process maintains a local variable $max_d_i$ initialized to $\Delta_i$, and each message $TERM()$ now carries this value. When a process $p_i$ receives a message $TERM(max_d, -,-,-)$ it executes the update statement $max_d_i \leftarrow \max(max_d, max_d_i)$. Finally, when the root process $p_r$ claims termination, it launches a second traversal of the tree to inform the other processes. We do not describe such a propagation of the value of $\Delta$ here. This will be done in Section 5.3 in the context of a parallel tree traversal.

### 4.2 Proof and cost of the algorithm

**Lemma 1.** Algorithm 1 is both collision-free and conflict-free.

**Proof** Let us first observe that, due to the assignment of the variable $state_i$ at line 09 (in the processing of a message $COLOR()$), or line 21 (in the processing of a message $TERM()$), a process $p_i$ is allowed to broadcast one and only one message when it executes line 13 or 15. It follows from the associated assignment of the control value 2 or 4 to $state_i$ (line 13 or 15), that $p_i$ cannot broadcast other messages $COLOR()$ or $TERM()$ before executing line 21 (i.e., before it receives a message $TERM()$).

Let us now observe that, due to line 04, a message $COLOR()$ broadcast by a process at line 13 is processed by a single destination process. Hence, the control flow generated by these messages remains sequential, moving sequentially from a parent process to a child process. Similarly, the control flow generated by the messages $TERM()$ (broadcast at line 15) moves sequentially from a child process $p_i$ to its parent process (whose identity is saved in $parent_i$).

The collision-freedom and conflict-freedom properties of the algorithm follow directly from the sequentiality of the control flow realized by the messages $COLOR()$ and $TERM()$. $\square$

**Lemma 2.** Algorithm 1 satisfies the Validity, Consistency, and Termination properties.

**Proof** Let us first prove the following claim.

Claim. For any $p_i$ and at any time, $|d1colors_i| < \Delta$.

Proof of the claim. Let us consider the local variable $d1colors_i$ of a process $p_i$. This variable is initialized at line 05, when $p_i$ receives a message $COLOR()$ for the first time. It then contains the color of its parent in
the tree. When the algorithm progresses, the color of a child $p_j$ of $p_i$ is added to $d1colors_i$ (line 20) when $p_i$ receives from $p_j$ a message $\text{TERM}$ carrying $p_j$’s color. It follows that, when $p_i$ issues its last broadcast of $\text{COLOR}(\text{child}, \cdot, \cdot, d1colors_i)$, $\text{child}$ is the identity of its only child without a color, and $d1colors_i$ contains the colors of all the other neighbors of $p_i$, hence, $|d1colors_i| < \Delta$. End of the proof of the claim.

The Validity property follows from the following observation. When a process $p_i$ selects its color, it follows from the previous claim and lines 06-07 that $|\{\text{parent} \cup d1colors\}| \leq \Delta$. Consequently, there is at least one free color in the set $\{0, \ldots, \Delta\}$.

To prove the Proper-Coloring property let us first observe that, due to (a) the initialization of $d1colors_j$ done when a process $p_j$ receives a message $\text{COLOR}$ from its parent (line 05), and (b) the updates that follow when it receives messages $\text{TERM}$ from its children (line 20), it follows that $d1colors_j$ contains the colors of the already colored neighbors of $p_j$. Hence, when a process $p_i$ selects a color (lines 06-07), the colors of the already colored processes at distance 2 from it are in the set $d1colors$ carried by the message $\text{COLOR}$ entailing $p_i$’s coloring. Due to line 06, $p_i$ does not select any of these colors.

The Termination property follows from the termination of the sequential traversal, at the end of which the root learns the algorithm has terminated.

The following theorem is an immediate consequence of the previous lemmas.

**Theorem 1.** Algorithm 1 is a collision-free and conflict-free distance-2 coloring algorithm for trees.

**Cost of the algorithm** (Let us recall that a process identity can be encoded with $O(\log n)$ bits.) There are two message types. A message $\text{TERM}$ carries two process identities and a color. A message $\text{COLOR}$ carries two process identities, a color, and set of at most $(\Delta - 1)$ colors. It follows that a message carries at most $2 \log n + \Delta \log \Delta$ bits.

A tree of maximal degree $\Delta$ has at least $x \geq \Delta - 1$ leaves. Let us first count the number of broadcasts of a message $\text{COLOR}$. The root issues at most $\Delta$ broadcasts; a process, which is neither the root nor a leaf, issues at most $(\Delta - 1)$ broadcasts; and a leaf issues no broadcast of such a message. It follows that there are $\Delta + (n - 1 - x)(\Delta - 1)$ broadcasts of a message $\text{COLOR}$. As $x \geq \Delta - 1$, the number of broadcasts of a message $\text{COLOR}$ is upper bounded by $\Delta + (n - \Delta)(\Delta - 1)$.

Each process which is not the root of the tree issues exactly one broadcast of a message $\text{TERM}$. It follows that there are $(n - 1)$ broadcasts of such a message.

## 5 Parallel Distance-2 Coloring of a Tree

This section presents a distributed distance-2 coloring for trees, which based on a parallel traversal of the tree network, with feedback (i.e., the dynamically defined root process that launches the network traversal learns of the end of the traversal). This algorithm can be seen as improvement of the previous algorithm in terms of time efficiency.

### 5.1 A parallel algorithm

**Underlying principle** Let us first observe that any two children of a process must be prevented from broadcasting simultaneously a message to their neighbors. This is because, being issued by processes at distance at most two, such simultaneous broadcasts will create a collision at least at the parent process.

The idea to prevent this vicinity/concurrency problem is first to direct a parent process to compute the colors of its children, and then, as soon as a process has obtained a color, to allow it to broadcast a message

---

*Lemma 2*
(COLOR() or TERM()) only during the time slots (rounds) associated with its color. To this end, each process uses the values provided by the global clock (CLOCK).

Messages and local variables The message types implementing the parallel tree traversal are the same as in Algorithm 1. Similarly, the local variables parent\textsubscript{i}, to\_color\textsubscript{i}, color\textsubscript{i}, sender\_cl\textsubscript{i}, and the constant neighbors\textsubscript{i}, have the same meaning as in Algorithm 1.

Each process \(p_i\) manages an additional variable nb\_cl\textsubscript{parent\textsubscript{i}}, initially 0, which will contain the number of colors needed to color its parent \(p_j\) and its neighbors (processes of neighbors\textsubscript{j}). This value is known to \(p_i\) when it receives its first message COLOR() (which defines its sender \(p_j\) as \(p_i\)’s parent). Each process has also a constant nb\_cl\textsubscript{i} = \(\Delta_i + 1\) which represents the number of colors needed to color itself and its neighbors.

```
Initialization: nb\_cl\textsubscript{i} = \(\Delta_i + 1\); state\textsubscript{i} \gets 0; max\_nb\_cl\textsubscript{i} \gets nb\_cl\textsubscript{i}.

(01) when START() is received do % a single process \(p_i\) receives this external message %
(02) \(p_i\) executes lines 04-08 as if it received the message COLOR\{\{(id\_i, cl\_i)\}, id\_i, -1, nb\_cl\textsubscript{i}\} where cl = (CLOCK + 1) mod nb\_cl\textsubscript{i}.

(03) when COLOR(pairs, sender, sender\_cl, nb\_cl\_parent) is received do
(04) if (COLOR()) already received then discard the message, do not execute lines 05-08 end if;
(05) parent\textsubscript{i} \gets sender; to\_color\textsubscript{i} \gets neighbors\textsubscript{i} \setminus \{sender\}; sender\_cl\textsubscript{i} \gets sender\_cl;
(06) color\textsubscript{i} \gets cl such that (id\_i, cl) \in pairs;
(07) nb\_cl\textsubscript{parent\textsubscript{i}} \gets nb\_cl\_parent;
(08) if to\_color\textsubscript{i} ≠ ∅ then state\textsubscript{i} \gets 1 else state\textsubscript{i} \gets 3 end if.

(09) when ((CLOCK \mod nb\_cl\_parent\textsubscript{i}) = color\textsubscript{i}) \& (state\textsubscript{i} \in \{1,3\}) do
(10) if (state\textsubscript{i} = 1)
(11) then pairs\_for\_children\textsubscript{i} \gets empty set of pairs;
(12) palette \gets sequence 0, 1,... without the colors color\textsubscript{i} and sender\_cl;
(13) for each k in to\_color\textsubscript{i}, do
(14) cl \gets first color in palette;
(15) suppress cl from palette and add (k, cl) to pairs\_for\_children\textsubscript{i};
(16) end for;
(17) broadcast COLOR(pairs\_for\_children\textsubscript{i}, id\_i, color\textsubscript{i}, nb\_cl\textsubscript{i}); state\textsubscript{i} \gets 2
(18) else broadcast TERM(parent\textsubscript{i}, id\_i); state\textsubscript{i} \gets 4 \% \(p_i\) and its neighbors are colored %
(19) end if.

(20) when TERM(dest, id\_i) is received do
(21) if (dest ≠ id\_i) then discard the message (do not execute lines 22-25) end if;
(22) to\_color\textsubscript{i} \gets to\_color\textsubscript{i} \setminus \{id\};
(23) if (to\_color\textsubscript{i} = ∅)
(24) then if (parent\textsubscript{i} = id\_i) then the root \(p_i\) claims termination else state\textsubscript{i} \gets 3 end if
(25) end if.
```

Algorithm 2: Parallel distributed distance-2 coloring of a tree (code for \(p_i\))

Description of the algorithm To simplify the presentation, we assume that the initial value of CLOCK is -1. As in the sequential version, a single process \(p_i\) receives the external message START(), that defines it as the root of the tree. Moreover, this reception entails the fictitious sending of the message COLOR\{\{(id\_r, cl\_r)\}, id\_r, -1, nb\_cl\_r\} where cl = (CLOCK + 1) mod nb\_cl\_r (line 02). Similarly to Al-
gorithm 1, according to the values carried by the message \textsc{color}(). \(p_r\) initializes its local variables and obtains the color \(c_l = 1\) (lines 05-07). It finally updates \(\text{state}_r\).

Then, when \(\text{CLOCK} = 1\), \(p_r\) executes lines 10-19. More generally, these lines are executed by any process \(p_i\) as soon as, after it received its first message \textsc{color}(), the color it obtained (\(\text{color}_i\)) is such that \(\text{color}_i = \text{CLOCK} \mod \text{nb} \cdot \text{cl}_{\text{parent}_i}\) (line 09). Hence, as the algorithm (a) allows a process to broadcast only at a round corresponding to its color, (b) allows only colored processes to broadcast \textsc{color}() or \textsc{term}() messages, and (c) ensures the distance-2 coloring property (see the proof) without any message collision or message conflict during its execution.

Let us consider a process \(p_i\) such that the predicate of line 09 is satisfied. There are two cases.

- If \(\text{state}_i = 1\), the neighbors of \(p_i\) are not colored. Process \(p_i\) computes then a color for each of its children (lines 11-16), and broadcasts a message \textsc{color}() to inform them of it (line 17). It is easy to see that the messages \textsc{color}() implements a parallel traversal of the tree from the root to the leaves. Then, \(p_i\) enters a waiting period by setting \(\text{state}_i\) to 2.

- If \(\text{state}_i = 3\), all neighbors of \(p_i\) (and all processes in their sub-trees) are colored. In this case, \(p_i\) forwards this information to its parent. As its local participation to the algorithm is terminated, \(p_i\) sets \(\text{state}_i\) to 4.

Finally, when a process \(p_i\) receives a message \textsc{term}() from one of its children, it first updates \(\text{to} \cdot \text{color}_i\) accordingly (line 22). If this set is empty, it claims termination if it is the root. Otherwise, it assigns 3 to \(\text{state}_i\), so that it will inform its parent of its local termination at the first time slot (round) at which its color satisfies the predicate of line 09.

5.2 Proof and cost of the algorithm

Lemma 3. Algorithm 2 is collision-free and conflict free.

Proof. Let us observe that a process \(p_i\) is allowed to broadcast a message \textsc{color}() (line 16) only if \(((\text{CLOCK} \mod \text{cl} \cdot \text{bound}) = \text{color}_i) \land (\text{state}_i = 1)\). As such a sending entails the assignment \((\text{state}_i \leftarrow 2)\) (and \(\text{state}_i\) never decreases), it follows that \(p_i\) issues at most one such broadcast. The same occurs for the broadcast of a message \textsc{term}().

Due to the initialization of its local variable \(\text{state}_i\), no process \(p_i\) can broadcast a message until one of them receives the message \textsc{start}(). Let us assume that (without loss of generality) that \(\text{CLOCK} = 0\) when a process a process \(p_i\) receives this message. It follows from the text of lines 01-08 that, before \(\text{CLOCK}\) increases, we have \(\text{color}_i = 1\) and \(\text{state}_i = 1\) (if the graph is not a singleton), or \(\text{color}_i = 1\) and \(\text{state}_i = 3\) (if the graph is a singleton).

Hence, when \(\text{CLOCK} = 1\), \(p_i\) executes lines 09-19 and broadcasts a message \textsc{color}() (line 17), or a message \textsc{term}() (line 18), while no other process can broadcast a message. Moreover, due to the color assignment done by \(p_i\) at lines 12-16, its neighbors obtain different colors when they receive the message \textsc{color}() from \(p_i\) at time \(\text{CLOCK} = 1\).

Due to the color computation done by \(p_i\) at line 12-16 (when \(\text{CLOCK} = 1\)), no two of its neighbors have the same color, and none of them has the same color as \(p_i\). It follows from the time predicate of line 09 that no two processes of the set \(\text{neighbors}_i \cup \text{id}_i\) can broadcast during the same time slot.

Let \(p_j\) be a neighbor of the root process \(p_i\). It follows from line 12 that, when \(p_j\) selects colors for its neighbors, it assigns them colors which are different among themselves and different from its own color and the color of \(p_i\). Hence, due the time predicate of line 09, it follows that no two processes of the set
neighbors_j \cup \{id_j\} can broadcast during the same time slot. The same reasoning applies to the neighbors of p_j, etc., which completes the proof of the lemma.

**Lemma 4.** Let p_i and p_j be two processes such that such parent_i = id_j. The color of p_i belong to the set \{0, ..., \Delta_j\}.

**Proof** Let p_i be any children of p_j. The color of p_i is defined by p_j when it executes the lines 12-16. The local palette of p_j is then the sequence 0, 1, ..., from which its own color (color_j) and the color of its neighbor which is parent (sender_cl) are suppressed (line 12). Hence, at most two integers (one in case of the root) are suppressed from the first \Delta_j + 1 non-negative integers from which the palette is built. Hence, p_j can color its neighbors with up to \Delta_j - 1 (\Delta_j if p_j is the root) colors with values less than \Delta_j + 1 and different from that of its parent.

**Lemma 5.** Algorithm 2 uses at most \Delta + 1 different colors to the processes, and no two processes at distance \leq 2 have the same color.

**Proof** Let us consider a process p_i. It has at most \Delta neighbors. It follows from lines 12-16, that all its neighbors (including the process from which it received the message COLOR()) are assigned different colors, and those are different from its color color_i. Hence no two processes at distance \leq 2 have the same color. As \Delta = \max(\Delta_1, \cdots, \Delta_n), it follows from Lemma 4 that at most (\Delta + 1) colors are used by the algorithm.

**Lemma 6.** Any process is colored, and (only after all processes are colored) this is known by the root process.

**Proof** Once a process received an external message START(), it becomes the root of the tree, it takes a color, and broadcasts a message COLOR() to its neighbors at line 17 as soon as the predicate of line 09 becomes satisfied. Then, each of these neighbor processes broadcasts a message COLOR() to their neighbors, etc.

As soon as its neighbors are colored, a process p_j is such that state_j = 3, and consequently it broadcasts a message TERM() at line 18. Let p_j be the parent process that broadcasts the message COLOR() received by p_i. When p_j has received message TERM() from all its children, it will proceed to state_j = 3 (line 24) and will broadcast TERM() at line 18 as soon as the time predicate of line 09 becomes satisfied.

It follows from the previous observations that the process that received the message START() eventually claims termination at line 24.

The following theorem is an immediate consequence of the previous lemmas.

**Theorem 2.** Algorithm 2 is a collision-free and conflict-free distance-2 coloring parallel algorithm for trees.

**Cost of the algorithm** Each process which is not a leaf issues one broadcast of a message COLOR(), and each process which is not the root issues one broadcast of a message TERM(). Let x be the number of leaves. There are consequently (2n - (x + 1)) broadcasts. As \(x \geq \Delta - 1\), the number of broadcasts is upper bounded by 2n - \Delta.

As far as time complexity is concerned, we have the following. Let d be the depth of the tree, and assume CLOCK = 0 when a process p_r receives the message START(), which defines it as the root of the tree. It follows from their color assignment (lines 12-16) that p_r’s children start one after the other at times 1, 2, ..., \Delta_r. Let p_x be the child of p_r that obtains the color \Delta_r. It broadcasts a message COLOR() to its
own children at time $\Delta_r + 1$, and its child with the highest color will do the same at time $\Delta_r + \Delta_i$. Etc. As this worst pattern can repeat along a path of the tree, it follows than process does not receive a message \texttt{COLOR}() before time $d\Delta$.

An analogous reasoning applies to the “return” messages \texttt{TERM()} starting from the leaves to the root. Hence, the time complexity is $O(d \Delta)$. (Let us remind that $d = O(\log \Delta n)$ when the tree is well-balanced.

### 5.3 Informing processes of termination

**Global vs local termination** Algorithm 2 implements a parallel distance-2 coloring, but only the root learns that the algorithm has terminated (global termination). A non-root process $p_i$ knows only that the sub-tree of which it is the root has terminated (local termination). This section enriches this algorithm so that any process learns about global termination.

The extended algorithm

This extended algorithm is made up of Algorithm 2 where line 18 is modified, and the statement “\texttt{when TERM(id) is received do ...}” (lines 20-24) is replaced by the statements described in Algorithm 3. Moreover, each process $p_i$ manages an additional local variable denoted $\texttt{max_{nb_{cl}i}}$, which is initialized to $\Delta_i + 1$.

When considering base Algorithm 2 and its extension Algorithm 3, the lines with the same number are the same in both algorithms, the lines suffixed by a “prime” are modified lines, and the lines N1-N7 are new lines.

\begin{verbatim}
(20') \textbf{when TERM(dest, id, max_{nb_{cl}i}) is received do}
(21) \hspace{1em} \textbf{if} (dest \neq id) \textbf{then} discard the message (do not execute lines 22-25) \textbf{end if};
(22) \hspace{1em} \texttt{to\_color}_i \leftarrow \texttt{to\_color}_i \setminus \{id\};
(N1) \hspace{1em} \texttt{max_{nb_{cl}i}} \leftarrow \max(\texttt{max_{nb_{cl}i}}, \texttt{max_{nb_{cl}d}});
(23) \hspace{1em} \textbf{if} (\texttt{to\_color}_i = \emptyset)
(24') \hspace{1.5em} \textbf{then if} (parent_i = id_i) \textbf{then} state_i \leftarrow 5 \textbf{else} state_i \leftarrow 3 \textbf{end if}
(25) \hspace{1em} \textbf{end if}.

(N2) \textbf{when} (\texttt{CLOCK} \mod \texttt{max_{nb_{cl}i}} = \texttt{color}_i) \land (\texttt{state}_i = 5) \textbf{do}
(N3) \hspace{1em} \textbf{if} (|\texttt{neighbors}_i| \neq 1) \textbf{then} broadcast \texttt{END}(id_i, \texttt{max_{nb_{cl}i}}) \textbf{end if}; \texttt{state}_i \leftarrow 6.

(N4) \textbf{when END(parent, max_{cl}) is received do}
(N5) \hspace{1em} \textbf{if} (parent = parent_i) \land (\texttt{state}_i = 4)
(N6) \hspace{1.5em} \texttt{max_{nb_{cl}i}} \leftarrow \max(\texttt{max_{nb_{cl}i}}, \texttt{max_{cl}}); \texttt{state}_i \leftarrow 5
(N7) \hspace{1em} \textbf{end if}.
\end{verbatim}

Algorithm 3: Parallel distance-2 coloring of a tree: propagation of the termination

The message \texttt{TERM(id)} broadcast by a process $p_i$ at line 18 must now carry the current value of $\texttt{max_{nb_{cl}i}}$, i.e., $p_i$ broadcasts \texttt{TERM(parent_i, id_i, max_{nb_{cl}i})}. The local variable $\texttt{max_{nb_{cl}i}}$ of a process $p_i$ is updated at line N1. In this way, starting from the leaves, these local variables allow the root to know the value $(\Delta + 1)$ (upper bound on the number of colors needed by a process to color itself and its neighbors).

When the root learns about global termination, it proceeds to $\texttt{state}_i = 5$ (line 24'). At this point, the value of its local variable $\texttt{max_{nb_{cl}i}}$ is $\Delta + 1$. Moreover, its new local state $\texttt{state}_i$ allows it to inform its children about global termination by broadcasting the message \texttt{END()} carrying the value $\Delta + 1$ (lines N2-N3).
Finally, when a process $p_i$, which is not the root (hence $state_i = 4$) receives an END ($parent$, $max_{cl}$) message, from its parent, it updates $max_{cl}$ and proceeds to $state_i = 5$ (lines N4-N7), which allows it to forward the END message to its children, if any (lines N2-N3). Let us notice that, as the children of a process $p_x$ do not broadcast END() messages during the same time slot (round), there is no collision of these messages at their parent. But since the parent simply discards these messages, a trivial optimization may consist in relaxing the collision-freedom constraint. Specifically, the children could send their END() messages in parallel as their parent does not need to receive them.\footnote{A similar optimization could be applied in the basic algorithm: processes could send COLOR messages in parallel and use the designated time slots only when propagating the TERM messages upstream.} Independently of the optimization, it follows from the propagation of the END() messages that, eventually, all the processes are such that $state_i = 6$. When this occurs, they learn about global termination.

**Remark** Let us consider the situation where, while the coloring algorithm has terminated (i.e., each process has obtained a color and knows $\Delta$), a new process $p_x$ wants to enter the tree and obtains a color. Let $p_i$ be the process chosen to be $p_x$’s parent. If $\Delta_i = \Delta$, $p_i$ cannot accept $p_x$ as a child (this would require an additional color). Differently, if $\Delta_i < \Delta$, it is easy to dynamically add $p_x$ as a child of $p_i$. To this end, $p_i$ takes the first color $cl$ in 0, 1, ..., $\Delta$, which is different from its own color and the colors of its neighbors. Then, during its next time slot, $p_i$ broadcasts the message NEW($cl$, $\Delta$), which, when received by $p_x$, gives it a proper color. Let us notice that this “join” does not require $p_x$ to have an identity. It is consequently possible for $p_i$ to also assign to $p_x$ an identity not belonging to \{$id_i$\} $\cup$ neighbors.

5.4 Merging two trees with the same maximal degree

Considering two trees $T_1$ and $T_2$, which have the same maximal degree $\Delta$, let $p_x$ be a process of $T_1$ and $p_y$ a process of $T_2$, both having a degree less than $\Delta$.

It is easy to see that, if \{$id_x$ $\notin$ (\{$id_y$ $\cup$ neighbors$_y$\})\} $\cap$ \{$id_y$ $\notin$ (\{$id_x$ $\cup$ neighbors$_x$\})\}, the trees $T_1$ and $T_2$ can be “added” to compose a single tree made up of $T_1$ and $T_2$ connected by the additional edge ($p_x$, $p_y$). This composition preserves the colors previously assigned by two independent executions of the algorithm, the one which assigned colors to $T_1$ and the one which assigned colors to $T_2$.

6 Conclusion

Synchronous networks where the time is decomposed in a sequence of time slots (rounds) and the communication operations are “broadcast a message to neighbors” and “receive a message a neighbor”, are prone to message collisions (which occur when two neighbors of a process send it a message during the same time slot), and message conflicts ((which occur when a process and one of its neighbors broadcast during the same time slot). Distance-2 coloring solves this problem by assigning a color to each process such that there is a matching of time slots with colors which prevents message collisions/conflicts from occurring.

This paper has presented a distributed algorithm which solves the distance-2 coloring problem in tree networks. This algorithm is based on a parallel tree traversal algorithm skeleton on which are grafted appropriate coloring assignments. It is itself collision/conflict-free. It uses only $\Delta + 1$ colors ($\Delta$ being the maximal degree of the network), which is optimal. Its time complexity is $O(d\Delta)$ (where $d$ is the depth of the tree). This algorithm does not require a process to initially know more than its identity and the ones of its neighbors. Moreover, any two processes at distance greater than 2 are not prevented from having the
same identity (which is important for scalability issues). Let us also notice that this algorithm is relatively simple (a first-class property).

A very challenging issue is now the design of a parallel collision/conflict-free distance-2 coloring algorithm for synchronous broadcast/receive systems whose communication graph is more general than a tree. As, when considering sequential computing, distance-2 coloring is an NP-complete problem, the design of such a distributed algorithm using a “reasonable” number of colors does not seem to be a “trivial” challenge. (A sequential algorithm suited to an arbitrary graph is presented in Appendix A.)

References

Algorithm 4 is a sequential distance-2 coloring algorithm for an arbitrary (connected) graph. The design of this algorithm is the same the one of Algorithm 1. It added complexity comes from the fact it allows the sequential control flow (implemented by the messages COLOR() and TERM() in Algorithm 1) to back track when a process discovers a coloring conflict. This backtracking is implemented by the messages CORRECT(), CORRECTED_COLOR(), and RESUME_COLORING().

Considering the network of Figure 1, An example of execution of Algorithm 4 is depicted in Table 1. Due to space restriction we abbreviate the following:

A sequential distributed algorithm for an arbitrary graph
Figure 1: A 5-process arbitrary network

- \( \text{br} = \text{broadcast operation} \),
- \( d_1 = d_1 \text{colors}_i \),
- \( d_2 = d_2 \text{colors}_i \),
- \( \text{CL}(p_a,p_b,c,z,S) = \text{COLOR}(p_a,p_b,c,z,S) \),
- \( \text{CRL}(p_a,p_b,c,S) = \text{CORRECT}(p_a,p_b,c,z,S) \),
- \( \text{CRCL}(p_a,p_b,c,S) = \text{CORRECTED}_{\text{CL}}(p_a,p_b,c,S) \),
- \( \text{RSM}_{\text{CL}}(p_a,p_b) = \text{RESUME}_{\text{CL}}(p_a,p_b) \),
- \( s_i = \text{state}_i \).

Process \( p_1 \) receives the message \text{START()} at round \(-1\). It broadcasts the message \text{COLOR}(id_1, id_1, -1, 0, \emptyset) to itself. It receives this message at round \(0\). It updates its local variables \( d_2 \) at line 02 (abbreviated as L2), \( d_1, s_1 \) and \( \text{color}_1 \) at line 06 (abbreviated as L6). This appears in the first row of the table where the value of \( \text{CLOCK} \) is \(0\). Then, when \( \text{CLOCK} \) progresses to \(1\), \( p_1 \) has \( \text{state}_1 = 2 \), therefore, it broadcasts the message \text{COLOR()} with appropriate parameters, where it proposes a color that is not in \( d_2 \cup d_1 \) to each of its neighbors, and subsequently enters \( \text{state}_1 = 0 \) (L16). This appears in the second row of the table where the value of \( \text{CLOCK} \) is \(1\). When \( p_2 \) and \( p_4 \) receive this message at round \(2\), they execute the associated processing at L2 and L6 for \( p_2 \) and at L10 for \( p_4 \). So, in this round \( p_2 \) updates its local variables \( d_2 \) at L2, \( d_1, s_2 \) and \( \text{color}_2 \) at L6. \( p_4 \) updates its local variables \( d_2 \) at L2, \( d_1 \), at L10. This appears in the third row of the table where \( \text{CLOCK} \) is \(2\). In round \(3\), \( p_2 \) has \( \text{state}_2 = 2 \), so it broadcasts the message \text{COLOR()} with appropriate parameters (L16) and gets \( \text{state}_2 = 0 \) (L16), Etc.

In round 6, \( p_4 \) finds that the color proposed by its neighbor \( p_3 \) (color 0 proposed in round 5) is in \( d_1 \), so it ”refuses” this color and gets \( \text{state}_4 = 1 \) (L4). In round 7, \( p_4 \) gets a color which is not in \( d_2 \cup d_1 \) (L11) and broadcasts the message \text{CORRECT}(id_3, id_4, 2, 0, \{0\}). In round 8, \( p_3 \) updates \( d_1 \) and \( d_2 \) and gets a new color (L31). Its state will allow it to broadcast the message \text{CORRECTED}_{\text{CL}()} (round 11). The broadcast of this message will trigger the broadcast of the message \text{RESUME}_{\text{CL}()} (round 15) to resume the coloring as described before.
