Abstract. A recent line of works – initiated by Gordon, Katz and Vaikuntanathan (Asiacrypt 2010) – gave lattice-based realizations of privacy-preserving protocols allowing users to authenticate while remaining hidden in a crowd. Despite five years of efforts, known constructions remain limited to static populations of users, which cannot be dynamically updated. For example, none of the existing lattice-based group signatures seems easily extendable to the more realistic setting of dynamic groups. This work provides new tools enabling the design of anonymous authentication systems whereby new users can register and obtain credentials at any time. Our first contribution is a signature scheme with efficient protocols, which allows users to obtain a signature on a committed value and subsequently prove knowledge of a signature on a committed message. This construction, which builds on the lattice-based signature of Böhl et al. (Eurocrypt’13), is well-suited to the design of anonymous credentials and dynamic group signatures. As a second technical contribution, we provide a simple, round-optimal joining mechanism for introducing new members in a group. This mechanism consists of zero-knowledge arguments allowing registered group members to prove knowledge of a secret short vector of which the corresponding public syndrome was certified by the group manager. This method provides similar advantages to those of structure-preserving signatures in the realm of bilinear groups. Namely, it allows group members to generate their public key on their own without having to prove knowledge of the underlying secret key. This results in a two-round join protocol supporting concurrent enrollments, which can be used in other settings such as group encryption.

Keywords. Lattice-based cryptography, anonymity, signatures with efficient protocols, dynamic group signatures, anonymous credentials.

1 Introduction

Lattice-based cryptography is currently emerging as a promising alternative to traditional public-key techniques. During the last decade, it has received a permanent interest (see \[70\] and references therein) due to its numerous advantages. Not only does it seemingly resist quantum attacks, it also provides
a better asymptotic efficiency than its relatives based on conventional number theory. While enabling advanced functionalities (like fully homomorphic or attribute-based/predicate encryption for circuits) that remain elusive outside the lattice world, lattice-based primitives tend to interact with zero-knowledge proofs less smoothly than their counterparts in abelian groups endowed with a bilinear map (see, e.g., or groups of hidden order). Arguably, this partially arises from the fact that lattices have far less algebraic structure than, e.g., pairing-friendly cyclic groups. It is not surprising that the most efficient zero-knowledge proofs for lattice-related languages take advantage of the extra algebraic structure available in the ring setting. A consequence of the scarcity of truly efficient zero-knowledge proofs in the lattice setting is that, in the context of anonymity and privacy-preserving protocols, lattice-based cryptography has undergone significantly slower development than in other areas like functional encryption. While natural realizations of ring signatures showed up promptly after the seminal work of Gentry, Peikert and Vaikuntanathan (GPV), viable constructions of lattice-based group signatures remained lacking until the work of Gordon, Katz and Vaikuntanathan in 2010. Despite recent advances in the area, lattice-based group signatures and other privacy-preserving primitives remain substantially less practical and powerful in terms of functionalities than their siblings based on traditional number theoretic problems for which solutions even exist outside the random oracle methodology. For example, we still have no convenient realization of group signature supporting dynamic groups or anonymous credentials.

In this paper, we address the latter two problems by first proposing a lattice-based signature with efficient protocols in the fashion of Camenisch and Lysyanskaya. To ease its use in the design of dynamic group signatures, we design a zero-knowledge argument system that allows a user to prove knowledge of a signature on a public key for which the user knows the underlying secret key.

**RELATED WORK.** Anonymous credentials were first suggested by Chaum and efficiently realized by Camenisch and Lysyanskaya. They involve one or more credential issuer(s) and a set of users who have a long-term secret key which constitutes a their digital identity and pseudonyms that can be seen as commitments to their secret key. Users can dynamically obtain credentials from an issuer that only knows users’ pseudonyms and obliviously certifies users’ secret keys as well as (optionally) a set of attributes. Later on, users can make themselves known to verifiers under a different pseudonym and demonstrate possession of the issuer’s signature on their secret key without revealing neither the signature nor the key. Anonymous credentials typically consist of a protocol whereby the user obtains the issuer’s signature on a committed message, another protocol for proving that two commitments open to the same value (which allows proving that the same secret underlies two distinct pseudonyms) and a protocol for proving possession of a secret message-signature pair.

The first efficient constructions were given by Camenisch and Lysyanskaya under the Strong RSA assumption or using bilinear groups. Other
solutions were subsequently given with additional useful properties such as non-interactivity [10], delegatability [9], a better efficiency in the private key setting [36], or support for efficient attributes [25] (see [28] and references therein). Anonymous credentials with attributes are often obtained by having the issuer obliviously sign a multi-block message ($\text{Msg}_1, \ldots, \text{Msg}_N$), where one block is the secret key while other blocks contain public or private attributes. Note that, for the sake of keeping the scheme compatible with zero-knowledge proofs, the blocks ($\text{Msg}_1, \ldots, \text{Msg}_N$) cannot be simply hashed before getting signed using a ordinary, single-block signature.

Group signatures are a central anonymity primitive, introduced by Chaum and van Heyst [38] in 1991, which allows members of a group managed by some authority to sign messages in the name of the entire group. At the same time, users remain accountable for the messages they sign since an opening authority can identify them if they misbehave.

Ateniese, Camenisch, Joye and Tsudik [6] provided the first scalable construction meeting the security requirements that can be intuitively expected from the primitive, although clean security notions were not available yet at that time. Bellare, Micciancio and Warinschi [11] filled this gap by providing suitable security notions for static groups, which were subsequently extended to the dynamic setting [4] by Kiayias and Yung [57] and Bellare, Shi and Zhang [13]. In these models, efficient schemes have been put forth in the random oracle model [57,42] (the ROM) and in the standard model [51,2,11].

Lattice-based group signatures were put forth for the first time by Gordon, Katz and Vaikuntanathan [49] whose solution had linear-size signatures in the number of group members. Camenisch, Neven and Rückert [33] extended [49] so as to achieve anonymity in the strongest sense. Laguillaumie et al. [58] decreased the signature length to be logarithmic in the number $N_{gs}$ of group members. While asymptotically shorter, their signatures remained space-consuming as, analogously to the Boyen-Waters group signature [20], their scheme encrypts each bit of the signer’s identity individually. Simpler and more efficient solutions with $O(\log N)$ signature size were given by Nguyen, Zhang and Zhang [67] and Ling, Nguyen and Wang [63]. In particular, the latter scheme [63] achieves significantly smaller signatures by encrypting all bits of the signer’s identity at once. Benhamouda et al. [14] described a hybrid group signature that simultaneously relies on lattice assumptions (in the ring setting) and discrete-logarithm-related assumptions. Recently, Libert, Ling, Nguyen and Wang [61] obtained substantial efficiency improvements via a construction based on Merkle trees which eliminates the need for GPV trapdoors [45]. For the time being, all known group signatures are designed for static groups and analyzed in the model of Bellare, Micciancio and Warinschi [11], where no new group member can be introduced after the setup phase. To date, it remains an open problem to design a lattice-based system that supports dynamically growing population of users in the models of [13,57].

---

3 By “dynamic setting”, we refer to a scenario where new group members can register at any time but, analogously to [13,57], we do not consider the orthogonal problem of user revocation here.
Our Contributions. Our first result is a lattice-based signature with efficient protocols for multi-block messages. Namely, we provide a way for a user to obtain a signature on a committed $N$-block message $(\text{Msg}_1, \ldots, \text{Msg}_N)$ as well as a protocol for proving possession of a valid message-signature pair. The signature and its companion protocols can serve as a building block for constructing lattice-based anonymous credentials and can potentially find other applications in the design of compact e-cash systems [26] under lattice assumptions. The main application that we consider in this paper is the construction of a lattice-based group signature scheme for dynamic groups. While less efficient than the recent proposal of [61], our scheme is competitive with the solution of Ling, Nguyen and Wang [63] which is one of the most efficient candidates based on standard (i.e., non-ideal) lattices in static groups. In particular, it features $O(\log N_{gs})$-size signatures for groups of up to $N_{gs}$ members and only lengthens the signatures of [63] by a (small) constant factor. We prove the security of our system in the random oracle model [12] under the Short Integer Solution (SIS) and Learning-With-Errors (LWE) assumptions.

To simplify the use of our signature scheme in the design of our dynamic group signatures, we also develop a zero-knowledge argument system allowing a group member to prove knowledge of a secret key (consisting of a short Gaussian vector) and a membership certificate issued by the group manager on the corresponding public key. This method can be seen as a lattice-based analogue of structure-preserving signatures in that it allows a signer to sign public keys without hashing them while remaining oblivious of the underlying secret key. Our zero-knowledge argument system and the signature scheme allow us to construct a dynamic joining protocol – which allows the group manager to dynamically introduce new group members by issuing a membership certificate on their public key – which does not require any proof of knowledge on behalf of the prospective user. As a result, the joining protocol is round-optimal: only one message is sent in each direction when the new user interacts with the group manager. Besides being the first lattice-based group signatures for dynamic groups, our scheme thus remains secure in the setting advocated by Kiayias and Yung [56], where many users want to join at the same time and concurrently interact with the group manager. We believe that, analogously to structure-preserving signatures [2, 1], the combination of our signature scheme and zero-knowledge arguments can serve as a building blocks for other primitives, including group encryption [55, 55] or adaptive oblivious transfer [50].

Our Techniques. Our signature scheme with efficient protocols builds on the SIS-based signature of Böhler et al. [16], which is itself a variant of Boyen’s signature [19]. Recall that the latter scheme involves a public key containing matrices $A, A_0, \ldots, A_\ell \in \mathbb{Z}_q^{m \times m}$ and signs an $\ell$-bit message $\text{Msg} \in \{0, 1\}^\ell$ by computing a short vector $v \in \mathbb{Z}_q^{2m}$ such that $[A | A_0 + \sum_{j=1}^\ell \text{Msg}[i]A_j] \cdot v = 0^m \mod q$. The variant of Böhler et al. [16] only uses a constant number of matrices $A, A_0, A_1 \in \mathbb{Z}_q^{m \times m}$.

\footnote{Note that each signature still requires the user to prove knowledge of his secret key. However, this is not a problem in concurrent settings as the proof of knowledge is made non-interactive via the Fiat-Shamir heuristic.}
Each signature is associated with a single-use tag \( \tau \) (which is only used in one signing query in the proof) and the public key involves an extra matrix \( D \in \mathbb{Z}_q^{n \times m} \) and a vector \( u \in \mathbb{Z}_q^n \). An message \( \text{Msg} \) is signed by first applying a chameleon hash function \( h = \text{CMHash}(\text{Msg}, s) \in \{0,1\}^m \) and signing \( h \) by computing a short \( \mathbf{v} \in \mathbb{Z}^m \) such that \([A | A_0 + \tau \cdot A_1] \cdot \mathbf{v} = u + D \cdot h \mod q.\)

Our scheme extends the latter scheme – modulo the use of a larger number of matrices \( \{A_j\}_{j=0}^\ell \) as in Boyen’s scheme – so that a signature on \( N \)-block message \( (\text{Msg}_1, \ldots, \text{Msg}_N) \in \{\{0,1\}\}^N \) consists of a tag \( \tau \in \{0,1\}^\ell \) and a short vector \( \mathbf{v} \in \mathbb{Z}^m \) such that \([A | A_0 + \sum_{j=1}^\ell \tau[j] \cdot A_j] \cdot \mathbf{v} = u + \text{CMHash}(\text{Msg}_1, \ldots, \text{Msg}_N, s),\) where the chameleon hash function computes \( \mathbf{c}_M = D_0 \cdot s + \sum_{k=1}^N D_k \cdot \text{Msg}_k \in \mathbb{Z}_q^n \), for some integer vector \( s \), before re-encoding \( \mathbf{c}_M \in \mathbb{Z}_q^n \) into \( \{0,1\}^m \).

In order to obtain a signature scheme akin to the one of Camenisch-Lysyanskaya \cite{CL01}, our idea is to have the tag \( \tau \in \{0,1\}^\ell \) play the same role as the prime exponent in Strong-RSA-based schemes \cite{HP02}. In the security proof of \cite{BCR05}, we are faced with two situations: either the adversary produces a signature on a fresh tag \( \tau' \), or it recycles a tag \( \tau^{(i)} \) used by the signing oracle for a new, unsigned message \( (\text{Msg}_1^*, \ldots, \text{Msg}_N^*) \). In the former case, the proof can proceed as in Boyen’s proof \cite{Boyen05}. In the latter case, the reduction must guess upfront which tag \( \tau^{(i)} \) the adversary will choose to re-use and find a way to properly answer the \( i \)-th signing query without using the vanished trapdoor (for other queries, the Agrawal \textit{et al.} technique \cite{AGR06} applies to compute a suitable \( \mathbf{v} \) using a trapdoor hidden in \( \{A_j\}_{j=0}^\ell \)). Böhler \textit{et al.} \cite{BCR05} solve this problem by “programming” the vector \( \mathbf{u} \in \mathbb{Z}_q^n \) in a special way and achieve full security using chameleon hashing.

To adapt this idea in the context of signatures with efficient protocols, we have to overcome two difficulties. The first one is to map \( \mathbf{c}_M \in \mathbb{Z}_q^n \) back in the domain of the chameleon hash function while preserving the compatibility with zero-knowledge proofs. To solve this problem, we extend a technique used in \cite{CL01} in order to build a “zero-knowledge-friendly” chameleon hash function. This function hashes a vector \( (\text{Msg}_1, \ldots, \text{Msg}_N) \) by choosing \( m = n \lceil \log q \rceil \) and outputting \( h = \text{bin}(D_0 \cdot s + \sum_{k=1}^N D_k \cdot \text{Msg}_k) \in \{0,1\}^m \) where, for any vector \( \mathbf{v} \in \mathbb{Z}_q^n \), \( \text{bin}(\mathbf{v}) \in \{0,1\}^m \) denotes the vector obtained by replacing each coordinate of \( \mathbf{v} \) by its binary decomposition. If we define the matrix \( \mathbf{H} = [1 \ 2 \ | \ \ldots \ | \ 2^{\lceil \log q \rceil}] \otimes \mathbf{I}_n \), we can prove that \( h = \text{CMHash}(\text{Msg}_1, \ldots, \text{Msg}_N, s, w) \) by demonstrating knowledge of short vectors \( (\text{Msg}_1, \ldots, \text{Msg}_N, s, h) \) such that \( \mathbf{H} \cdot \mathbf{w} = D_0 \cdot s + \sum_{k=1}^N D_k \cdot \text{Msg}_k \), which boils down to arguing knowledge of a solution to the ISIS problem \cite{DGH01}. Then, we extend the techniques of \cite{AFG00} to prove knowledge of \( (\tau, \mathbf{v}, s) \) and \( (\text{Msg}_1, \ldots, \text{Msg}_N) \) satisfying \([A \ | \ A_0 + \sum_{j=1}^\ell \tau[j] \cdot A_j] \cdot \mathbf{v} = u + \text{CMHash}(\text{Msg}_1, \ldots, \text{Msg}_N, s),\) without revealing any of the witnesses. In a nutshell, we show that most of the involved statements are equivalent to asserting that a short integer vector \( \mathbf{x} \) satisfies an equation of the form \( \mathbf{P} \cdot \mathbf{x} = \mathbf{v} \mod q \), for some public matrix \( \mathbf{P} \) and vector \( \mathbf{v} \), and belongs to a set \text{VALID} of short vectors with a particular structure. While the small-norm property of \( \mathbf{x} \) is provable using standard techniques (e.g., \cite{AFG00}), we prove its membership of \text{VALID} by leveraging the combinatorial properties of Stern-like protocols \cite{DGH01} and playing with their underlying permutations.
The second problem arises when, analogously to \[31\], we extend the scheme into a protocol for signing committed messages. In this case, the signer must first additively re-randomize the user’s commitment \(c_U = D_0 \cdot s + \sum_{k=1}^{N} D_k \cdot \text{Msg}_k\) before generating a signature on the hidden messages. This is indeed necessary to provide the reduction with a backdoor allowing to correctly answer the \(i\)th signing query by “programming” the randomness \(s\) of the chameleon hash. One difficulty is that the randomness of the commitment (like the one of the chameleon hash function) is a discrete Gaussian vector which, unlike vectors of finite field elements, cannot easily be programmed in a statistically indistinguishable manner: this technique indeed affects the standard deviation of the Gaussian vector \(s\) in exactly one signing query. Using integer commitments, Camenisch and Lysyanskaya \[31\] address a similar problem by letting the signer’s randomness be exponentially larger than the initial randomness of the user’s commitment: this allows the distribution of the “programmed” randomness to be statistically close to that of the sum of the two contributions of the signer and the user in the real scheme. While a similar technique, called “smudging”, has been used in the lattice setting by Asharov et al. \[5\], Lemma 2.1], it requires the modulus \(q\) to be exponentially large as well. Here, we adopt a more efficient solution, inspired by the results of Bai et al. \[7\], which is to apply an analysis based on the Rényi divergence rather than the statistical distance. In short, the probability preservation property of the Rényi divergence tells us that, if some event \(E\) occurs with noticeable probability in some probability space \(P\), so does it in a different probability space \(Q\) for which the second order Rényi divergence \(R_2(P||Q)\) is sufficiently small. In our setting, \(R_2(P||Q)\) is precisely polynomially bounded since the two probability spaces only diverge in one signing query.

Our dynamic group signature scheme avoids these difficulties because the group manager does not have to obliviously sign messages: instead of signing the user’s secret key as usually done in anonymous credentials, the group manager creates a membership certificate consisting of a signature on the user’s public key. Our zero-knowledge argument system accommodates the requirements of our group signature in the following way. In the joining protocol that dynamically introduces new group members, the prospective user \(i\) chooses a membership secret consisting of a short discrete Gaussian vector \(z_i \in \mathbb{Z}^m\). This user generates a public syndrome \(v_i = F \cdot z_i \mod q\), for some public matrix \(F\), which constitutes his public key. In order to certify \(v_i \in \mathbb{Z}_q^n\), the group manager computes a coordinate-wise binary expansion of \(v_i\) so as to obtain a vector \(\text{bin}(v_i) \in \{0, 1\}^{n \lceil \log q \rceil}\). The latter vector is then signed using our variant of the Böhl et al. signature. Using the resulting signature \((\tau, v, s)\) as a membership certificate, the group member will be able to sign a message by proving that: (i) He holds a valid signature \((\tau, v, s)\) on some secret binary message \(\text{bin}(v_i)\); (ii) The latter vector \(\text{bin}(v_i)\) is the binary expansion of some syndrome \(v_i \in \mathbb{Z}^m_q\) of which he knows a GPV pre-image \(z_i \in \mathbb{Z}^m\). We remark that condition (ii) can be proved by providing evidence that, if we define \(H = \mathbb{I}_n \otimes [1 \mid 2 \mid \ldots \mid 2^{\lceil \log q \rceil}]\), we have \(v_i = H \cdot \text{bin}(v_i) = F \cdot z_i \mod q\), for some short vector \(z_i \in \mathbb{Z}^m\) and some binary \(\text{bin}(v_i) \in \{0, 1\}^{n \lceil \log q \rceil}\). As was previously noticed in \[63\], the framework of Stern-like protocols \[74\] and its
extensions to lattices \([4, 102]\) is well-suited to efficiently argue such statements, especially for conditions of the form \(\binom{v_i}{v_j} \in \{0,1\}^n \left[ \log q \right]\). The fact that the underlying chameleon hash function smoothly interacts with Stern-like zero-knowledge proofs is the property that maintains the user’s capability of efficiently proving knowledge of the underlying secret key.

**Organization.** In the forthcoming sections, we first provide some background in Section 2. Our lattice-based signature with efficient protocols is presented in Section 3 where we also give protocols for obtaining a signature on a committed message and proving knowledge of a signature on a committed message. Section 4 uses our signature scheme in the design of dynamic group signatures. In Section 5, we finally provide the details of the zero-knowledge arguments for the statements to be proved in our protocols of Section 3 and 4.

## 2 Background and Definitions

In the following, all vectors are denoted in bold lower-case letters, whereas bold upper-case letters will be used for matrices. If \(\mathbf{b} \in \mathbb{R}^n\), its euclidean norm will be denoted by \(\|\mathbf{b}\|\). This notation is extended to matrices \(\mathbf{B} \in \mathbb{R}^{m \times n}\) with columns \((\mathbf{b}_i)_{i \leq n}\) by \(\|\mathbf{B}\| = \max_{i \leq n} \|\mathbf{b}_i\|\). If \(\mathbf{B}\) is full column-rank, we let \(\tilde{\mathbf{B}}\) denote the Gram-Schmidt orthogonalisation of \(\mathbf{B}\).

When \(\mathcal{S}\) is a finite set, we denote by \(U(\mathcal{S})\) the uniform distribution over \(\mathcal{S}\) and by \(x \leftarrow U(\mathcal{S})\) the action of sampling \(x\) according to this distribution.

### 2.1 Lattices

A (full-rank) lattice \(L\) is the set of all integer linear combinations of some linearly independent basis vectors \((\mathbf{b}_i)_{i \leq n}\) belonging to some \(\mathbb{R}^n\). We work with \(q\)-ary lattices, for some prime \(q\).

**Definition 1.** Let \(m \geq n \geq 1\), a prime \(q \geq 2\) and \(\mathbf{A} \in \mathbb{Z}_q^{n \times m}\) and \(\mathbf{u} \in \mathbb{Z}_q^n\), define \(A_q^\perp(\mathbf{A}) := \{\mathbf{e} \in \mathbb{Z}^m \mid \exists \mathbf{s} \in \mathbb{Z}_q^n \text{ s.t. } \mathbf{A}^T \cdot \mathbf{s} = \mathbf{e} \mod q\}\) as well as

\[
A_q^1(\mathbf{A}) := \{\mathbf{e} \in \mathbb{Z}^m \mid \mathbf{A} \cdot \mathbf{e} = \mathbf{0}^n \mod q\}, \quad A_q^n(\mathbf{A}) := \{\mathbf{e} \in \mathbb{Z}^m \mid \mathbf{A} \cdot \mathbf{e} = \mathbf{u} \mod q\}
\]

For any \(\mathbf{t} \in A_q^0(\mathbf{A})\), \(A_q^n(\mathbf{A}) = A_q^1(\mathbf{A}) + \mathbf{t}\) so that \(A_q^n(\mathbf{A})\) is a shift of \(A_q^1(\mathbf{A})\).

For a lattice \(L\), a vector \(\mathbf{c} \in \mathbb{R}^n\) and a real \(\sigma > 0\), define \(\rho_{\sigma, \mathbf{c}}(\mathbf{x}) = \exp(-\pi \|\mathbf{x} - \mathbf{c}\|^2/\sigma^2)\). The discrete Gaussian distribution of support \(L\), parameter \(\sigma\) and center \(\mathbf{c}\) is defined as \(D_{L, \sigma, \mathbf{c}}(\mathbf{y}) = \rho_{\sigma, \mathbf{c}}(\mathbf{y})/\rho_{\sigma, \mathbf{c}}(L)\) for any \(\mathbf{y} \in L\). We denote by \(D_{L, \sigma}(\mathbf{y})\) the distribution centered in \(\mathbf{c} = \mathbf{0}\). We will extensively use the fact that samples from \(D_{L, \sigma}\) are short with overwhelming probability.

**Lemma 1** ([3, Le. 1.5]). For any lattice \(L \subseteq \mathbb{R}^n\) and positive real number \(\sigma > 0\), we have \(\Pr_{\mathbf{b} \leftarrow D_{L, \sigma}}[\|\mathbf{b}\| \leq \sqrt{n}\sigma] \geq 1 - 2^{-\Omega(n)}\).

As shown by Gentry et al. [13], Gaussian distributions with lattice support can be sampled from efficiently, given a sufficiently short basis of the lattice.
Lemma 2 (\cite{23} Le. 2.3). There exists a PPT (probabilistic polynomial-time) algorithm GPVSample that takes as inputs a basis $B$ of a lattice $L \subseteq \mathbb{Z}^n$ and a rational $\sigma \geq ||B|| \cdot \Omega(\sqrt{\log n})$, and outputs vectors $b \in L$ with distribution statistically close to $A$ as inputs a matrix $A \in \mathbb{Z}_q^{n \times m}$ and a basis $T_A$ of $A_q^\perp(A)$ such that $A$ is within statistical distance $2^{-Q(n)}$ to $U(\mathbb{Z}_q^{n \times m})$, and $||T_A|| \leq O(\sqrt{n \log q})$.

Lemma 3 (\cite{31} Th. 3.2). There exists a PPT algorithm TrapGen that takes as inputs $1^n, 1^m$ and an integer $q \geq 2$ with $m \geq \Omega(n \log q)$, and outputs a matrix $A \in \mathbb{Z}_q^{n \times m}$ and a basis $T_A$ of $A_q^\perp(A)$ such that $A$ is within statistical distance $2^{-Q(n)}$ to $U(\mathbb{Z}_q^{n \times m})$, and $||T_A|| \leq O(\sqrt{n \log q})$.

Lemma 2 is often combined with the sampler from Lemma 2. Micciancio and Peikert \cite{60} recently proposed a more efficient approach for this combined task, which should be preferred in practice but, for the sake of simplicity, we present our schemes using TrapGen.

We also make use of an algorithm that extends a trapdoor for $A \in \mathbb{Z}_q^{n \times m}$ to a trapdoor of any $B \in \mathbb{Z}_q^{n \times m}$ whose left $n \times m$ submatrix is $A$.

Lemma 4 (\cite{34} Le. 3.2). There exists a PPT algorithm ExtBasis that takes as inputs a matrix $B \in \mathbb{Z}_q^{n \times m}$ whose first $m$ columns span $\mathbb{Z}_q^n$, and a basis $T_A$ of $A_q^\perp(A)$ where $A$ is the left $n \times m$ submatrix of $B$, and outputs a basis $T_B$ of $A_q^\perp(B)$ with $||T_B|| \leq ||T_A||$.

In our security proofs, analogously to \cite{19,19} we also use a technique due to Agrawal, Boneh and Boyen \cite{103} that implements an all-but-one trapdoor mechanism (akin to the one of Boneh and Boyen \cite{17}) in the lattice setting.

Lemma 5 (\cite{31} Th. 19). There exists a PPT algorithm SampleRight that takes as input matrices $A, C \in \mathbb{Z}_q^{n \times m}$, a low-norm matrix $R \in \mathbb{Z}_q^{m \times m}$, a short basis $T_C \in \mathbb{Z}_q^{m \times m}$ of $A_q^\perp(C)$, a vector $u \in \mathbb{Z}_q^n$ and a rational $\sigma \geq ||T_C|| \cdot \Omega(\sqrt{\log n})$, and outputs vectors $b \in \mathbb{Z}_q^{2m}$ such that $[A | A \cdot R + C] \cdot b = u \mod q$ and with distribution statistically close to $D_{L,\sigma}$ where $L$ denotes the shifted lattice $\{x \in \mathbb{Z}^{2m} : [A | A \cdot R + C] \cdot x = u \mod q\}$.

2.2 Computational Problems

The security of our schemes provably relies (in the ROM) on the assumption that both algorithmic problems below are hard, i.e., cannot be solved in polynomial time with non-negligible probability and non-negligible advantage, respectively.

Definition 2. Let $m, q, \beta$ be functions of a parameter $n$. The Short Integer Solution problem $\text{SIS}_{m,q,\beta}$ is as follows: Given $A \leftarrow U(\mathbb{Z}_q^{n \times m})$, find $x \in A_q^\perp(A)$ with $0 < ||x|| \leq \beta$.

Definition 3. Let $q, \alpha$ be functions of a parameter $n$. For $s \in \mathbb{Z}_q^n$ (a secret), the distribution $A_{q,\alpha,s}$ over $\mathbb{Z}_q^n \times \mathbb{Z}_q$ is obtained by sampling $a \leftarrow U(\mathbb{Z}_q^n)$ and (a noise) $e \leftarrow D_{\mathbb{Z},\alpha,q}$, and returning $(a, (a \cdot s) + e)$. The Learning With Errors problem $\text{LWE}_{q,\alpha}$ is as follows: For $s \leftarrow U(\mathbb{Z}_q^n)$, distinguish between arbitrarily many independent samples from $U(\mathbb{Z}_q^n \times \mathbb{Z}_q)$ and the same number of independent samples from $A_{q,\alpha,s}$.
If \( q \geq \sqrt{n} \beta \) and \( m, \beta \leq \text{poly}(n) \), then standard worst-case lattice problems with approximation factors \( \gamma = O(\beta \sqrt{n}) \) reduce to \( \text{SIS}_{m,q,\beta} \) (see, e.g., [45], Se. 9). Similarly, if \( \alpha q = O(\sqrt{n}) \), standard worst-case lattice problems with approximation factors \( \gamma = O(\alpha/n) \) quantumly reduce [71,69,23] to \( \text{LWE}_{q,\alpha} \).

3 A Lattice-Based Signature with Efficient Protocols

Our scheme can be seen as a variant of the Böhl et al. signature [16], where each signature is a triple \((\tau, \nu, s)\), made of a tag \( \tau \in \{0,1\}^\ell \) and integer vectors \((\nu, s)\) satisfying \([A \mid A_0 + \sum_{j=1}^\ell \tau[j] \cdot A_j] \cdot \nu = u + D \cdot h \mod q\), where \(A, D \in \mathbb{Z}_q^{n \times m}\) are public random matrices and \(h \in \{0,1\}^m\) is a chameleon hash of the message which is computed using randomness \(s\). A difference is that, while [16] uses a short single-use tag \( \tau \in \mathbb{Z}_q\), we need the tag to be an \( \ell\)-bit string \( \tau \in \{0,1\}^\ell \) which will assume the same role as the prime exponent of Camenisch-Lysyanskaya signatures [31] in the security proof.

We show that a suitable chameleon hash function makes the scheme compatible with Stern-like zero-knowledge arguments [62,46,4] for arguing possession of a valid message-signature pair. Section 5 shows how to translate such a statement into asserting that a short witness vector \(x\) with a particular structure satisfies a relation of the form \(P \cdot x = \nu \mod q\), for some public matrix \(P\) and vector \(\nu\). The underlying chameleon hash can be seen as a composition of the SIS-based chameleon hash of [31] Section 4.1 with a technique used in [68,61]. On input of a message \((m_1, \ldots, m_N, s)\), it outputs the binary decomposition of \(D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k \mod q\), for some discrete Gaussian vector \(s\).

3.1 Description

We assume that messages are vectors of \(N\) blocks \(\text{Msg} = (m_1, \ldots, m_N)\), where each block is an \(2m\)-bit string \(m_k = m_k[1] \ldots m_k[2m] \in \{0,1\}^{2m}\) for \(k \in \{1, \ldots, N\}\).

For each vector \(\nu \in \mathbb{Z}_q^L\), we denote by \(\text{bin}(\nu) \in \{0,1\}^{L \cdot \lceil \log q \rceil}\) the vector obtained by replacing each coordinate of \(\nu\) by its binary representation.

**Keygen**\((1^\lambda, 1^N)\): Given a security parameter \(\lambda > 0\) and the number of blocks \(N = \text{poly}(\lambda)\), choose the following parameters: \(n = \Theta(\lambda)\); a sufficiently large modulus \(q = \text{poly}(n)\); dimension \(m = 2n \lceil \log q \rceil\); an integer \(\ell = \Theta(\lambda)\); and Gaussian parameters \(\sigma = \Omega(\sqrt{n \log q \log n})\), \(\sigma_0 = 2\sqrt{2}(N + 1)\sigma_m^{3/2}\), and \(\sigma_1 = \sqrt{\sigma_0^2 + \sigma^2}\). Define the message space as \(\{0,1\}^{2m}\).

1. Run \(\text{TrapGen}(1^n, 1^m, q)\) to get \(A \in \mathbb{Z}_q^{n \times m}\) and a short basis \(T_A\) of \(A_q^\perp(A)\).
   - This basis allows computing short vectors in \(A_q^\perp(A)\) with a Gaussian parameter \(\sigma\). Next, choose \(\ell + 1\) random \(A_0, A_1, \ldots, A_\ell \leftarrow U(\mathbb{Z}_{q}^{n \times m})\).
2. Choose random matrices \(D \leftarrow U(\mathbb{Z}_q^{n \times m})\), \(D_0, D_1, \ldots, D_N \leftarrow U(\mathbb{Z}_q^{2n \times 2m})\) as well as a random vector \(u \leftarrow U(\mathbb{Z}_q^n)\).
   - The private key consists of \(SK := T_A\) and the public key is \(PK := (A, \{A_j\}_{j=0}^\ell, \{D_k\}_{k=0}^N, D, u)\).
\textbf{Sign}(SK, \text{Msg}): \text{To sign an} \ N\text{-block message } \text{Msg} = (m_1, \ldots, m_N) \in \{0,1\}^{2mN},

1. Choose a random binary string \( \tau \leftarrow U\{0,1\}^\ell \). Then, using \( SK := TA \), compute a short delegated basis \( T_\tau \in \mathbb{Z}_{2m}^{n \times 2m} \) for the matrix

\[ A_\tau = [A | A_0 + \sum_{j=1}^\ell \tau[j]A_j] \in \mathbb{Z}_{2m}^{n \times 2m}. \tag{1} \]

2. Choose a discrete Gaussian vector \( s \leftarrow D_{\mathbb{Z}_{2m}, \sigma_1} \). Compute the vector \( c_M \in \mathbb{Z}_{2n}^q \) as a chameleon hash of \( (m_1, \ldots, m_N) \). Namely, compute

\[ c_M = D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k \in \mathbb{Z}_q^{2n}, \]

which is used to define \( u_M = u + D \cdot \text{bin}(c_M) \in \mathbb{Z}_q^n \). Then, using the delegated basis \( T_\tau \in \mathbb{Z}_{2m}^{n \times 2m} \), sample a short vector \( v \in \mathbb{Z}_{2m}^{2m} \) in \( D_{\mathbb{Z}_q}^{2m}(A_\tau) \). Output the signature \( \text{sig} = (\tau, v, s) \in \{0,1\}^{\ell} \times \mathbb{Z}_{2m}^{2m} \times \mathbb{Z}_q^{2m} \).

\textbf{Verify}(PK, \text{Msg}, \text{sig}): \text{Given } PK, \text{ a message } \text{Msg} = (m_1, \ldots, m_N) \in \{0,1\}^{mN} \text{and a purported signature } \text{sig} = (\tau, v, s) \in \{0,1\}^{\ell} \times \mathbb{Z}_{2m}^{2m} \times \mathbb{Z}_q^{2m}, \text{return } 1 \text{ if}

\[ A_\tau \cdot v = u + D \cdot \text{bin}(D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k) \mod q. \tag{2} \]

and \( ||v|| < \sigma \sqrt{2m}, ||s|| < \sigma_1 \sqrt{2m} \).

When the scheme is used for obliviously signing committed messages, the security proof follows Bai et al. [7] in that it applies an argument based on the Rényi divergence in one signing query. This argument requires to sample \( s \) from a Gaussian distribution whose standard deviation \( \sigma_1 \) is polynomially larger than \( \sigma \).

We note that, instead of being included in the public key, the matrices \( \{D_k\}_{k=0}^N \) can be part of common public parameters shared by many signers. Indeed, only the matrices \( \{A, \{A_i\}_{i=0}^{\ell m}\} \) should be specific to the user who holds the secret key \( SK = TA \). In Section 3.3, we use a variant where \( \{D_k\}_{k=0}^N \) belong to public parameters.

3.2 Security Analysis

The security analysis in Theorem 1 requires that \( q > \ell \).

\textbf{Theorem 1.} The scheme is secure under chosen-message attacks under the SIS assumption.

\textit{Proof.} The prove the result, we will distinguish two kinds of attacks:

\textbf{Type I attacks} are attacks where, in the adversary’s forgery \( \text{sig}^* = (\tau^*, v^*, s^*) \), \( \tau^* \) did not appear in any output of the signing oracle.
Type II attacks are such that, in the adversary’s forgery $\text{sig}^* = (\tau^*, v^*, s^*)$, $\tau^*$ is recycled from an output $\text{sig}(\ell^*) = (\tau(\ell^*), v(\ell^*), s(\ell^*))$ of the signing oracle, for some index $\ell^* \in \{1, \ldots, Q\}$. However, if $\text{Msg}^* = (m_1^*, \ldots, m_N^*)$ and $\text{Msg}(\ell^*) = (m_1^{(\ell^*)}, \ldots, m_N^{(\ell^*)})$ denote the forgery message and the $\ell^*$-th signing query, respectively, we have $D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* \neq D_0 \cdot s(\ell^*) + \sum_{k=1}^{N} D_k \cdot m_k^{(\ell^*)}$.

Type III attacks are those where the adversary’s forgery $\text{sig}^* = (\tau^*, v^*, s^*)$ recycles $\tau^*$ from an output $\text{sig}(\ell^*) = (\tau(\ell^*), v(\ell^*), s(\ell^*))$ of the signing oracle (i.e., $\tau(\ell^*) = \tau^*$ for some index $\ell^* \in \{1, \ldots, Q\}$) and we have the collision

$$D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* = D_0 \cdot s(\ell^*) + \sum_{k=1}^{N} D_k \cdot m_k^{(\ell^*)}.$$  \hspace{1cm} (3)

Type III attacks imply a collision for the chameleon hash function of Kawachi et al. [54]: if (3) holds, a short vector of $\beta$ assumption holds for $\Lambda$. If $\text{Msg}^* = (m_1^*, \ldots, m_N^*)$ denote the forgery message and the $\ell^*$-th signing query, respectively, we have $D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* \neq D_0 \cdot s(\ell^*) + \sum_{k=1}^{N} D_k \cdot m_k^{(\ell^*)}$.

Theorem 2 requires that at least one block $m_k$ of the forgery message is 1 while the same bit is 0 at some specific signing query. We will show that the correctness of this encoding can be efficiently proved using Stern-like protocols.

3.3 Protocols for Signing a Committed Value and Proving Possession of a Signature

We first show a two-party protocol whereby a user can interact with the signer in order to obtain a signature on a committed message.

In order to prove that the scheme still guarantees unforgeability for obliviously signed messages, we will assume that each message block $m_k \in \{0, 1\}^m$ is obtained by encoding the actual message $M_k = M_k[1] \ldots M_k[m] \in \{0, 1\}^m$ as $m_k = (M_k[1], M_k[1], \ldots, M_k[m], M_k[m])$. Namely, each 0 (resp. each 1) is encoded as a pair $(1, 0)$ (resp. $(0, 1)$). The reason for this encoding is that the proof of Theorem 2 requires that at least one block $m_k^*$ of the forgery message is 1 while the same bit is 0 at some specific signing query. We will show that the correctness of this encoding can be efficiently proved using Stern-like protocols.

To sign committed messages, a first idea is exploit the fact that our signature...
of Section 3.1 blends well with the SIS-based commitment scheme suggested by Kawachi et al. [64]. In the latter scheme, the commitment key consists of matrices \((D_0, D_1) \in \mathbb{Z}_q^{2n \times 2m} \times \mathbb{Z}_q^{2n \times 2m}\), so that message \(m \in \{0,1\}^{2m}\) can be committed to by sampling a Gaussian vector \(s \leftarrow D_{2^{2m}, \sigma}\) and computing \(C = D_0 \cdot s + D_1 \cdot m \in \mathbb{Z}_q^{2n}\). This scheme extends to commit to multiple messages \((m_1, \ldots, m_N)\) at once by computing \(C = D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k \in \mathbb{Z}_q^{2n}\) using a longer commitment key \((D_0, D_1, \ldots, D_N) \in (\mathbb{Z}_q^{2n \times 2m})^{N+1}\). It is easy to see that the resulting commitment remains statistically hiding and computationally binding under the SIS assumption.

In order to make our construction usable in the definitional framework of Camenisch et al. [28], we assume common public parameters (i.e., a common reference string) and encrypt all witnesses of which knowledge is being proved under a public key included in the common reference string. The resulting ciphertexts thus serve as statistically binding commitments to the witnesses. To enable this, the common public parameters comprise public keys \(G_0 \in \mathbb{Z}_q^{n \times \ell}\), \(G_1 \in \mathbb{Z}_q^{n \times 2m}\) for multi-bits variants of the dual Regev cryptosystem [45] and all parties are withheld access to the underlying private keys. In order to prove that the content of a perfectly hiding commitment \(c_m\) is consistent with encrypted values, the protocols of Ling et al. [63] come in handy.

**Global-Setup:** Let \(B = \sqrt{n} \omega(\log n)\) and let \(\chi\) be a \(B\)-bounded distribution (i.e., it outputs integer samples with norm at most \(B\) with overwhelming probability). Let \(p > \sigma \cdot \omega(\log n)\) upper-bounds entries of vectors sampled from the distribution \(D_{2^{2m}, \sigma}\). Generate two public keys for the dual Regev encryption scheme in its multi-bit variant. These keys consist of a public random matrix \(B \leftarrow U(\mathbb{Z}_q^{n \times m})\) and random matrices \(G_0 = B \cdot E_0 \in \mathbb{Z}_q^{n \times \ell}\), \(G_1 = B \cdot E_1 \in \mathbb{Z}_q^{n \times 2m}\), where \(E_0 \in \mathbb{Z}_q^{m \times \ell}\) and \(E_1 \in \mathbb{Z}_q^{m \times 2m}\) are short Gaussian matrices with columns sampled from \(D_{2^{2m}, \sigma}\). These matrices will be used to encrypt integer vectors of dimension \(\ell\) and \(2m\), respectively. Finally, generate public parameters \(CK := \{D_k\} \in (\mathbb{Z}_q^{n \times 2m})^N\) consisting of uniformly random matrices \(D_k \leftarrow U(\mathbb{Z}_q^{2^{2m} \times 2m})\) for a statistically hiding commitment to vectors in \((\{0,1\}^{2m})^N\). Return public parameters consisting of

\[
\text{par} := \{B \in \mathbb{Z}_q^{n \times m}, G_0 \in \mathbb{Z}_q^{n \times \ell}, G_1 \in \mathbb{Z}_q^{n \times 2m}, CK\}.
\]

**Protocol:** The signer \(S\), who holds a key pair \(PK := \{A, \{A_j\}_{j=0}, D, u\}, SK := T_A\), interacts with the user \(U\) who has a message \((m_1, \ldots, m_N)\), in the following interactive protocol.

1. \(U\) samples \(s' \leftarrow D_{2^{2m}, \sigma}\) and computes \(c_m = D_0 \cdot s' + \sum_{k=1}^N D_k \cdot m_k \in \mathbb{Z}_q^{2n}\) which is sent to \(S\) as a commitment to \((m_1, \ldots, m_N)\). In addition, \(U\) encrypts \(\{m_k\}_{k=1}^N\) and \(s'\) under the dual-Regev public key \((B, G_1)\) by computing for all \(k \in \{1, \ldots, N\}:
\]
\[
c_k = (c_{k,1}, c_{k,2}) = (B^T \cdot s_{k,0} + e_{k,1}, G_1^T \cdot s_{k,0} + e_{k,2} + m_k \cdot \lfloor q/2 \rfloor) \in \mathbb{Z}_q^{m} \times \mathbb{Z}_q^{2m}
\]

\(4\)
Prove the following protocol.

Note that, if both parties faithfully run the protocol, the user obtains a valid signature pair. In order to prove possession of a message-signature pair, the user runs the protocol constructed in Section 5.1 and uses \( \ell \) arguments, where \( \ell \) is the security parameter, in Section 5.3, where we demonstrate that, together with other zero-knowledge protocols used in this work, it can be derived from a Stern-like protocol constructed in Section 5.1.

2. If the argument of step 1 properly verifies, \( S \) samples \( s'' \leftarrow D_{Z^{2m} \sigma_0} \) and computes a vector \( u_m = u + D \cdot \bin(c_m + D_0 \cdot s'') \in \mathbb{Z}_n^\ell \). Next, \( S \) randomly picks \( \tau \leftarrow \{0, 1\}^\ell \) and uses \( T_A \) to compute a delegated basis \( T_\tau \in \mathbb{Z}_{2m}^{2 \times 2m} \) for the matrix \( A_\tau \in \mathbb{Z}_q^{2m \times 2m} \) of \( 1 \). Using \( T_\tau \in \mathbb{Z}_{2m}^{2 \times 2m} \), \( S \) samples a short vector \( v \in \mathbb{Z}_{2m}^\ell \) in \( D_{A^\top(A_\tau), \sigma}^\ell \). It returns the vector \( (\tau, v, s'') \) to \( U \).

3. \( U \) computes \( s = s' + s'' \) over \( \mathbb{Z} \) and verifies that
\[
A_\tau \cdot v = u + D \cdot \bin(D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k) \mod q.
\]

If so, it outputs \( \tau, v, s \). Otherwise, it outputs \( \perp \).

Note that, if both parties faithfully run the protocol, the user obtains a valid signature \( \tau, v, s \) for which the distribution of \( s \) is \( D_{Z^{2m} \sigma_1} \), where \( \sigma_1 = \sqrt{\sigma^2 + \sigma_0^2} \).

In order to prove possession of a message-signature pair, the user runs the following protocol.

**Prove:** On input of a signature \( \tau, v = (v^T, v_2^T, s) \in \{0, 1\}^\ell \times \mathbb{Z}_{2m}^2 \times \mathbb{Z}_{2m}^{2m} \) on the message \( (m_1, \ldots, m_N) \), the user does the following.

1. Using \( (B, G_0) \) and \( (B, G_1) \) generate perfectly binding commitments to \( \tau \in \{0, 1\}^\ell \), \( \{m_k\}_{k=1}^N \), \( v_1, v_2 \in \mathbb{Z}^m \) and \( s \in \mathbb{Z}_{2m}^m \). Namely, compute
\[
c_\tau = (c_{\tau,1}, c_{\tau,2})
= (B^T \cdot s_\tau + e_{\tau,1}, G_0^T \cdot s_\tau + e_{\tau,2} + \tau \cdot \bin(q/2)) \in \mathbb{Z}_{q}^m \times \mathbb{Z}_{q}^\ell,
\]
\[
c_k = (c_{k,1}, c_{k,2})
= (B^T \cdot s_{k,0} + e_{k,1}, G_1^T \cdot s_{k,0} + e_{k,2} + m_k \cdot \bin(q/2)) \in \mathbb{Z}_{q}^m \times \mathbb{Z}_{q}^{2m}
\forall k \in \{1, \ldots, N\}.
While Böhler will re-use $\tau$ vectors, however, we can still view $s\{\text{matrices}\}$ the adaptively-chosen signed message ($D$ hash function mechanism which is implicitly realized by the matrix prove security against non-adaptive forgers, we directly use a built-in chameleon answer exactly one signing query in a different way, without using the trapdoor. SIS for solving simulation trapdoor of Agrawal et al.

One issue is that this results in a different distribution for the vector $s$ sampled from a Gaussian distribution
centered away from \(0^{2m}\). Since this specific situation occurs only once during the simulation, we can apply a result proved in \([60]\) which upper-bounds the Rényi divergence between two Gaussian distributions with identical standard deviations but different centers. By choosing the standard deviation \(\sigma_1\) of \(s \in \mathbb{Z}^{2m}\) to be polynomially larger than that of the columns of matrices \(\{R_k\}_{k=1}^N\), we can keep the Rényi divergence between the two distributions of \(s\) (i.e., the one of the simulation and the one of the real game) sufficiently small to apply the probability preservation property (which still gives a polynomial reduction since the argument must only be applied on one signing query). Namely, the latter implies that, if the Rényi divergence \(R_2(s^{\text{real}}||s^{\text{sim}})\) is polynomial, the probability that the simulated vector \(s^{\text{sim}} \in \mathbb{Z}^{2m}\) passes the verification test will only be polynomially smaller than in the real game and so will be the adversary’s probability of success.

Another option would have been to keep the statistical distance between \(s^{\text{real}}\) and \(s^{\text{sim}}\) negligible using the smudging technique of \([5]\). However, this would have implied to use an exponentially large modulus \(q\) since \(\sigma_1\) should have been exponentially larger than the standard deviations of the columns of \(\{R_k\}_{k=1}^N\).

**Theorem 2.** Under the SIS assumption, the above protocols are secure protocols for obtaining a signature on a committed message and proving possession of a valid message-signature pair. (The proof is given in Appendix B.4.)

**Theorem 3.** The scheme provides anonymity under the LWE assumption. (The proof is given in Appendix B.5.)

4 A Dynamic Lattice-Based Group Signature

In this section, the signature scheme of Section 3 is used to design a group signature for dynamic groups using the syntax and the security model of Kiayias and Yung [57], which is recalled in Appendix A.

In the notations hereunder, for any positive integers \(n\) and \(q \geq 2\), we define the “Powers-of-2” matrix \(H_{n \times n[\log q]} \in \mathbb{Z}_{q}^{n \times n[\log q]}\) as:

\[
H = \begin{bmatrix}
1 & 2 & 4 & \ldots & 2^{[\log q]-1} \\
1 & 2 & 4 & \ldots & 2^{[\log q]-1} \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
1 & 2 & 4 & \ldots & 2^{[\log q]-1}
\end{bmatrix} \otimes I_n
\]

Also, for each vector \(v \in \mathbb{Z}_{q}^n\), we define \(\text{bin}(v) \in \{0, 1\}^{n[\log q]}\) to be the vector obtained by replacing each entry of \(v\) by its binary expansion. Note that \(v = H_{n \times n[\log q]} \cdot \text{bin}(v)\) for any \(v \in \mathbb{Z}_{q}^n\).

In our scheme, each user’s group membership certificate is a signature generated by the group manager on the user’s public key. Since the group manager only needs to sign known (rather than committed) messages, we can use a simplified version of the signature, where the underlying chameleon hash function does not
have to choose the discrete Gaussian vector \( \mathbf{s} \) with a larger standard deviation than other vectors.

A key component of the scheme is the two-message joining protocol whereby the group manager admits new group members by signing their public key. The first message is sent by the new user \( U_i \) who samples a membership secret consisting of a short vector \( \mathbf{z}_i \sim D_{Z_{4m}^m} \) (where \( m = 2n \log q \)), which is used to compute a syndrome \( \mathbf{v}_i = \mathbf{F} \cdot \mathbf{z}_i \in Z_q^{4n} \) for some public matrix \( \mathbf{F} \in Z_q^{4n \times 4m} \). This syndrome \( \mathbf{v}_i \in Z_q^{4n} \) must be signed by \( U_i \) using his long term secret key \( \text{usk}[i] \) (as in [57,19], we assume that each user has a long-term key \( \text{upk}[i] \) for a regular signature scheme, which is registered in some PKI) and will uniquely identify \( U_i \). In order to generate a membership certificate for \( \mathbf{v}_i \in Z_q^{4n} \), the group manager \( GM \) signs its binary expansion \( \text{bin}(\mathbf{v}_i) \in \{0,1\}^{4n\log q} \) using the signature scheme of Section 3.

Equipped with his membership certificate \((\tau, \mathbf{d}, \mathbf{s}) \in \{0,1\}^\ell \times Z^{2m} \times Z^{2m} \), the new group member \( U_i \) can sign a message using a Stern-type protocol for demonstrating his knowledge a valid certificate for which he also knows the secret key associated with the certified public key \( \mathbf{v}_i \in Z_q^{4n} \). This boils down to providing evidence that the membership certificate is a valid signature on some binary message \( \text{bin}(\mathbf{v}_i) \in \{0,1\}^{4n\log q} \), for which he also knows a short \( \mathbf{z}_i \in Z_q^{4m} \) such that \( \mathbf{v}_i = \mathbf{H}_{4n \times 2m} \cdot \text{bin}(\mathbf{v}_i) = \mathbf{F} \cdot \mathbf{z}_i \in Z_q^{4n} \).

Interestingly, the process does not require any proof of knowledge of the membership secret \( \mathbf{z}_i \) during the joining phase, which is round-optimal. Analogously to the Kiayias-Yung technique [56] and constructions based on structure-preserving signatures [2], the joining protocol thus remains secure in environments where many users want to register at the same time in concurrent sessions.

We remark that a similar Stern-like protocol could also be directly used to prove knowledge of a Boyen signature [19] on a binary expansion of the user’s syndrome \( \mathbf{v}_i \in Z_q^{4n} \) while preserving the user’s ability to prove knowledge of a short \( \mathbf{z}_i \in Z_q^{4m} \) such that \( \mathbf{F} \cdot \mathbf{z}_i = \mathbf{v}_i \mod q \). However, this would require considerably longer private keys containing \( 4n \log q \) matrices \( \{\mathbf{A}_j\}_{j=0}^\ell \) of dimension \( n \times m \) each (i.e., we would need \( \ell = \Theta(n \cdot \log q) \)). In contrast, by using the signature scheme of Section 3 we only need the group public key \( \mathcal{Y} \) to contain \( \ell = \log N_{\mathcal{G}} \), matrices in \( Z_q^{n \times m} \). Since the number of users \( N_{\mathcal{G}} \) is polynomial, we have \( \log N_{\mathcal{G}} \ll n \), which results in a much more efficient scheme.

### 4.1 Description of the Scheme

**Setup**\((1^\lambda, 1^{N_{\mathcal{G}}})\): Given a security parameter \( \lambda > 0 \) and the maximal number of group members \( N_{\mathcal{G}} = 2^k \in \text{poly}(\lambda) \), choose parameters \( n = O(\lambda); \) modulus \( q = \text{poly}(n); \) dimensions \( m = 2n \log q \); Gaussian parameter \( \sigma = \Omega(\sqrt{n \log q \log n}); \) infinity norm bounds \( \beta = \sigma \omega(\sqrt{\log m}) \) and \( B = \sqrt{n} \omega(\log n) \). Let \( \chi \) be a \( B \)-bounded distribution. Choose a hash function \( H : \{0,1\}^t \rightarrow \{1,2,3\}^t \) for some \( t = \omega(\log n) \), which will be modeled as a random oracle in the security analysis. Then, do the following,
1. Generate a key pair for the signature scheme of Section 3.1 for signing single-block messages. Namely Run TrapGen($1^n, 1^m, q$) to get $A \in \mathbb{Z}^{n \times m}_q$ and a short basis $T_A$ of $A_q^\perp(A)$. This basis allows computing short vectors in $A_q^\perp(A)$ with a Gaussian parameter $\sigma \geq \|T_A\| \cdot \sqrt{\log m}$. Next, choose random matrices $A_0, A_1, \ldots, A_r, D \leftarrow U(\mathbb{Z}_q^{n \times m})$, $D_0, D_1 \leftarrow U(\mathbb{Z}^{2n \times 2m}_q)$ and a vector $u \leftarrow U(\mathbb{Z}_q^n)$.

2. Choose an additional random matrix $F \leftarrow U(\mathbb{Z}^{4n \times 4m}_q)$ uniformly. Looking ahead, this matrix will be used to ensure security against framing attacks.

3. Generate a master key pair for the Gentry-Peikert-Vaikuntanathan IBE scheme in its multi-bit variant. This key pair consists of a statistically uniform matrix $B \in \mathbb{Z}^{n \times m}_q$ and a short basis $T_B \in \mathbb{Z}^{m \times m}$ of $A_q^\perp(B)$. This basis will allow us to compute GPV private keys with a Gaussian parameter $\sigma_{GPV} \geq \|T_B\| \cdot \sqrt{\log m}$.

4. Choose a one-time signature scheme $\Pi^{OTS} = (\mathcal{G}, \mathcal{S}, \mathcal{V})$ and a hash function $H_0 : \{0, 1\}^* \rightarrow \mathbb{Z}^{n \times 2m}_q$, that will be modeled as random oracles in the security analysis.

The group public key is defined as

$$\mathcal{Y} := (A, \{A_j\}_{j=0}^r, B, D, D_0, D_1, F, u, \Pi^{OTS}, H, H_0).$$

The opening authority’s private key is $\mathcal{S}_{OA} := T_B$ and the private key of the group manager consists of $\mathcal{S}_{GM} := T_A$. The algorithm outputs $(\mathcal{Y}, \mathcal{S}_{GM}, \mathcal{S}_{OA})$.

**Join($GM, U_i$):** the group manager GM and the prospective user $U_i$ run the following interactive protocol: $[\text{id}_{\text{user}}(\lambda, \mathcal{Y}), J_{GM}(\lambda, St, \mathcal{Y}, \mathcal{S}_{GM})]$

1. $U_i$ samples a discrete Gaussian vector $z_i \leftarrow D_{\mathbb{Z}^m, \sigma}$ and computes $v_i = F \cdot z_i \in \mathbb{Z}^{4n}_q$. He sends the vector $v_i \in \mathbb{Z}^{4n}_q$, whose binary representation $\text{bin}(v_i)$ consists of $4n[\log q] = 2m$ bits, together with an ordinary digital signature $\text{sig}_i = \text{Sign}_{\text{sk}[\mathcal{Y}]}(v_i)$ to GM.

2. $J_{GM}$ verifies that $v_i$ was not previously used by a registered user and that $\text{sig}_i$ is a valid signature on $v_i$ w.r.t. $\text{upk}[i]$. It aborts if this is not the case. Otherwise, $GM$ chooses a fresh $\ell$-bit identifier $\text{id}_i = \text{id}_i[1] \ldots \text{id}_i[\ell] \in \{0, 1\}^\ell \ell$ and uses $\mathcal{S}_{GM} = T_A$ to certify $U_i$ as a new group member. To this end, GM defines the matrix

$$A_{\text{id}_i} = \begin{bmatrix} A & A_0 + \sum_{j=1}^\ell \text{id}_i[j] A_j \end{bmatrix} \in \mathbb{Z}^{n \times 2m}_q. \tag{6}$$

Then, GM runs $T_{\text{id}_i} \leftarrow \text{ExtBasis}(A_{\text{id}_i}, T_A)$ to obtain a short delegated basis $T_{\text{id}_i}$ of $A_q^\perp(A_{\text{id}_i}) \in \mathbb{Z}^{2m \times 2m}_q$. Finally, GM samples a short vector $s_i \leftarrow D_{\mathbb{Z}^m, \sigma}$ and uses the obtained delegated basis $T_{\text{id}_i}$ to compute a short vector $d_i = \begin{bmatrix} d_{i,1} \\ d_{i,2} \end{bmatrix} \in \mathbb{Z}^{2m}_q$ such that

$$A_{\text{id}_i} d_i = \begin{bmatrix} A & A_0 + \sum_{j=1}^\ell \text{id}_i[j] A_j \end{bmatrix} \cdot d_i = u + D \cdot \text{bin}(D_0 \cdot \text{bin}(v_i) + D_1 \cdot s_i) \mod q. \tag{7}$$
The triple \((id_i, d_i, s_i)\) is sent to \(U_i\). Then, \(J_{\text{user}}\) verifies that the received \((id_i, d_i, s_i)\) satisfies (7) and that \(\|d_i\|_\infty \leq \beta, \|s_i\|_\infty \leq \beta\). If these conditions are not satisfied, \(J_{\text{user}}\) aborts. Otherwise, \(J_{\text{user}}\) defines the membership certificate as \(\text{cert}_i = (id_i, d_i, s_i)\). The membership secret \(\text{sec}_i\) is defined to be \(\text{sec}_i = z_i \in \mathbb{Z}^{4n}\). \(J_{\text{GM}}\) stores transcript \(_i = (v_i, \text{cert}_i, i, \text{upk}[i], \text{sig}_i)\) in the database \(\text{St}_{\text{trans}}\) of joining transcripts.

Sign(\(\mathcal{V}, \text{cert}_i, \text{sec}_i, M\)): To sign \(M \in \{0,1\}^*\) using \(\text{cert}_i = (id_i, d_i, s_i)\), where \(d_i = [d_{i,1}^T | d_{i,2}^T] \in \mathbb{Z}^{2m}\) and \(s_i \in \mathbb{Z}^{2m}\), as well as the membership secret \(\text{sec}_i = z_i \in \mathbb{Z}^{4m}\), the group member \(U_i\) generates a one-time signature key pair \((VK, SK) \leftarrow S(n)\) and conducts the following steps.

1. Compute \(G_0 = H_0(VK) \in \mathbb{Z}_q^{n \times 2m}\) and use it as an IBE public key to encrypt \(\text{bin}(v_i) \in \{0,1\}^{2m}\), where \(v_i = F \cdot z_i \in \mathbb{Z}_q^{4n}\) is the syndrome of \(\text{sec}_i = z_i \in \mathbb{Z}^{4m}\), the group member \(U_i\) generates a one-time signature key pair \((VK, SK) \leftarrow S(n)\) and conducts the following steps.

\[ c_{v_i} = (c_1, c_2) = (B^T \cdot e_0 + x_1, \ G_0^T \cdot e_0 + x_2 + \text{bin}(v_i) \cdot [q/2]) \] (8)

for randomly chosen \(e_0 \leftarrow \chi^n, x_1 \leftarrow \chi^m, x_2 \leftarrow \chi^{2m}\). Notice that, as in the construction of (5), the columns of \(G_0\) can be interpreted as public keys for the multi-bit version of the dual Regev encryption scheme.

2. Run the protocol in Section 5 so as to prove the knowledge of identifier \(id_i = id[i_1], \ldots, id[\ell] \in \{0,1\}^\ell\), vectors \(s_i \in \mathbb{Z}^{2m}, d_{i,1}, d_{i,2} \in \mathbb{Z}^{m}, z_i \in \mathbb{Z}^{4m}\) with infinity norm bound \(\beta\): \(e_0 \in \mathbb{Z}_q^n, x_1 \in \mathbb{Z}_q^m, x_2 \in \mathbb{Z}_q^{2m}\) with infinity norm bound \(B\) and \(\text{bin}(v_i) \in \{0,1\}^{2m}, w_i \in \{0,1\}^{1m}\), that satisfy (8) as well as

\[ A \cdot d_{i,1} + A_0 \cdot d_{i,2} + \sum_{j=1}^{\ell} \{id[j] \cdot d_{i,2}\} \cdot A_j - D \cdot w_i = u \in \mathbb{Z}_q^n \] (9)

and

\[ H_{2n \times m} \cdot w_i = D_0 \cdot \text{bin}(v_i) + D_1 \cdot s_i \in \mathbb{Z}_q^{2n} \] (10)

\[ F \cdot z_i = H_{4n \times 2m} \cdot \text{bin}(v_i) \in \mathbb{Z}_q^{4n}. \] (11)

The protocol is repeated \(t = \omega(\log n)\) times in parallel to achieve negligible soundness error, and then made non-interactive using the Fiat-Shamir heuristic as a triple \(\pi_K = (\{\text{Comm}_{K,j}\}_{j=1}^\ell, \text{Chall}_K, \{\text{Resp}_{K,j}\}_{j=1}^\ell)\), where \(\text{Chall}_K = H(M, VK, c_{v_i}, \{\text{Comm}_{K,j}\}_{j=1}^\ell) \in \{1,2,3\}^\ell\)

4. Compute a one-time signature \(\text{sig} = S(SK, (c_{v_i}, \pi_K))\).

Output the signature that consists of

\[ \Sigma = (VK, c_{v_i}, \pi_K, \text{sig}). \] (12)

Verify(\(\mathcal{V}, M, \Sigma\)): Parse \(\Sigma\) as in (12). Then, return 1 if and only if:

(i) \(\mathcal{V}(VK, (c_{v_i}, c_s, c_id, \pi_K), \text{sig}) = 1\);

(ii) The proof of knowledge \(\pi_K\) properly verifies.
Otherwise, return 0.

**Open**($\mathcal{O}$, $\mathcal{OA}$, $M$, $\Sigma$): Parse $\mathcal{OA}$ as $T_B \in \mathbb{Z}^{m \times m}$ and $\Sigma$ as in [12].

1. Compute $G_0 = H_0(\text{VK}) \in \mathbb{Z}^{n \times 2m}$. Then, using $T_B$ to compute a small-norm matrix $E_{0,\text{VK}} \in \mathbb{Z}^{m \times 2m}$ such that $B \cdot E_{0,\text{VK}} = G_0 \mod q$.
2. Using $E_{0,\text{VK}}$, decrypt $c_v$ to obtain a string $\text{bin}(v) \in \{0,1\}^{2m}$ (i.e., by computing $\lfloor (c_2 - E_{0,\text{VK}} \cdot c_1)/(q/2) \rfloor$).
3. Determine if the $\text{bin}(v) \in \{0,1\}^{2m}$ obtained at step 2 corresponds to a vector $v = H_{\text{trans}} \cdot \text{bin}(v) \mod q$ that appears in a record transcript$_i = (v, \text{cert}_i, i, \text{upk}_i[sig_i])$ of the database $\text{St}_{\text{trans}}$ for some $i$. If so, output the corresponding $i$ (and, optionally, $\text{upk}_i[sig_i]$). Otherwise, output $\bot$.

We remark that the scheme readily extends to provide a mechanism whereby the opening authority can efficiently prove that signatures were correctly opened at each opening operation. The difference between the dynamic group signature models suggested by Kiayias and Yung [57] and Bellare et al. [13] is that, in the latter, the opening authority ($\mathcal{OA}$) must be able to convince a judge that the $\text{Open}$ algorithm was run correctly. Here, such a mechanism can be realized using the techniques of public-key encryption with non-interactive opening [41].

4.2 Security Analysis

Due to the fact that the number of public matrices $\{A_j\}_{j=0}^\ell$ is only logarithmic in $N_{\text{gs}} = 2^\ell$ instead of being linear in the security parameter $\lambda$, the proof of security against misidentification attacks (as defined in Appendix A) cannot rely on the security of our signature scheme in a modular manner. The reason is that, at each run of the $\text{Join}$ protocol, the group manager maintains a state and, instead of choosing the $\ell$-bit identifier $\text{id}$ uniformly in $\{0,1\}^\ell$, it chooses an identifier that has not been used yet. Since $\ell \ll \lambda$ (given that $N_{\text{gs}} = 2^\ell$ is polynomial in $\lambda$), we thus have to prove security from scratch. However, the strategy of the reduction is exactly the same as in the security proof of the signature scheme.

**Theorem 4.** The scheme is secure against misidentification attacks under the SIS assumption. (The proof is available in Appendix C.1)

**Theorem 5.** The scheme is secure against framing attacks under the SIS assumption. (The proof is given in Appendix C.2)

**Theorem 6.** Suppose that $\Pi^{\text{OTS}}$ is a strongly unforgeable one-time signature. In the random oracle model, the scheme provides CCA-anonymity under the LWE$_{q,\alpha}$ assumption. Namely for any PPT adversary $A$ with advantage $\varepsilon$, there exists an algorithm $B$ solving the LWE$_{q,\alpha}$ problem with advantage at most $2^{-\Omega(n)}$ smaller. (The proof is given in Appendix C.3)
5 Supporting Zero-Knowledge Argument Systems

This section provides a general framework that allows obtaining zero-knowledge arguments of knowledge for the majority of relations appearing in lattice-based cryptography. Since lattice-based cryptosystems are built upon the hardness of the SIS and LWE problems, the relations among objects of the schemes are typically represented by modular linear equations. Thanks to the linearity property, we can often unify the given equations into just one equation of the form:

\[ \mathbf{P} \cdot \mathbf{x} = \mathbf{v} \mod q, \quad (13) \]

where \((\mathbf{P}, \mathbf{v})\) are public and \(\mathbf{x}\) is a secret vector (or matrix) that possesses some constraints to be proven in zero-knowledge, e.g., its smallness (like a SIS solution, an LWE noise) or a special arrangement of its entries. Starting from this high-level observation, we look for a tool that handles these constraints well.

Stern’s protocol [73], originally proposed in the context of code-based cryptography, appears to be well-suited for our purpose. Stern’s main idea is simple, yet elegant: To prove that a binary vector \(\mathbf{x}\) has the fixed-Hamming-weight constraint, simply send the verifier a random permutation \(\pi(\mathbf{x})\) which should guarantee that the constraint is satisfied while leaking no additional information about \(\mathbf{x}\). Ling et al. [62] developed this idea to handle the smallness constraint, via a technique called Decomposition-Extension. This technique decomposes a vector with small infinity norm \(B \geq 1\) into \(\lfloor \log_2 B \rfloor + 1\) vectors with infinity norm 1, and then, extends these vectors into elements of sets that are closed under permutations. Several subsequent works [59][63][61] employed Stern’s idea and Ling et al.’s technique in different contexts, but did not address the applicability and flexibility of the protocol in an abstract, generalized manner.

In Section 5.1, we abstract Stern’s protocol to capture many relations that naturally appear in lattice-based cryptography. In particular, we demonstrate that the argument systems used in Sections 5.3, 5.4 and 5.5 can all be derived from this abstract protocol. Our strategy might be of wide interest, since it yields a blueprint for proving many other intricate relations in a simple manner.

5.1 Abstracting Stern’s Protocol

Let \(D, L, q \geq 2\) be positive integers let \(\text{VALID}\) be a subset of \(\{-1, 0, 1\}^L\). Suppose that \(\mathcal{S}\) is a finite set such that one can associate every \(\pi \in \mathcal{S}\) with a permutation \(T_{\pi}\) of \(L\) elements, satisfying the following condition:

\[ \mathbf{x} \in \text{VALID} \iff T_{\pi}(\mathbf{x}) \in \text{VALID}. \quad (14) \]

We aim to construct a \(s\text{ZKAoK}\) for the following abstract relation:

\[ \mathcal{R}_{\text{abstract}} = \{ (\mathbf{M}, \mathbf{c}), \mathbf{x} \in \mathbb{Z}_q^{D \times L} \times \mathbb{Z}_q^D \times \text{VALID} : \mathbf{M} \cdot \mathbf{x} = \mathbf{c} \mod q \}. \]

Note that, Stern’s original protocol corresponds to the special case when \(\text{VALID} = \{ \mathbf{x} \in \{0, 1\}^L : \text{wt}(\mathbf{x}) = k \}\) (where \(\text{wt}(\cdot)\) denotes the Hamming weight
and \( k < L \) is a given integer), \( S = S_L \) - hereunder the set of all permutations of \( L \) elements, and \( T_\pi(x) = \pi(x) \).

The equivalence in \([14]\) plays a crucial role in proving in ZK that \( x \in \text{VALID} \):
To do so \( P \) samples \( \pi \leftarrow U(\mathbb{S}) \) and let \( V \) check that \( T_\pi(x) \in \text{VALID} \), while the later cannot learn any additional information about \( x \) thanks to the randomness of \( \pi \). Furthermore, to prove in ZK that the linear equation holds, \( P \) samples a masking vector \( r \leftarrow U(\mathbb{Z}_q^L) \), sends \( y = x + r \mod q \), and convinces \( V \) instead that \( M \cdot y = M \cdot r + c \mod q \).

The interactive protocol between \( P(M,c,x) \) and \( V(M,c) \), which employs a statistically hiding and computationally binding string commitment scheme \text{COM} (e.g., the SIS-based one from \([54]\)), is described in Figure 1:

\[
\begin{align*}
1. \text{Commitment:} & \quad P \text{ samples } r \leftarrow U(\mathbb{Z}_q^L), \pi \leftarrow U(\mathbb{S}) \text{ and randomness } \rho_1, \rho_2, \rho_3 \text{ for } \text{COM}. \text{ Then } P \text{ sends the commitment } \text{CMT} = (C_1, C_2, C_3) \text{ to } V, \text{ where } \\
& \quad C_1 = \text{COM}(\pi, M \cdot r; \rho_1), \quad C_2 = \text{COM}(T_\pi(r); \rho_2), \quad C_3 = \text{COM}(T_\pi(x + r); \rho_3). \\
2. \text{Challenge:} & \quad V \text{ sends a challenge } Ch \leftarrow U(\{1, 2, 3\}) \text{ to } P. \\
3. \text{Response:} & \quad \text{Depending on } Ch, P \text{ sends the response } \text{RSP} \text{ computed as follows:} \\
& \quad Ch = 1: \text{ Let } t_i = T_\pi(x), t_r = T_\pi(r), \text{ and } \text{RSP} = (t_x, t_r, \rho_2, \rho_3). \\
& \quad Ch = 2: \text{ Let } \pi_2 = \pi, y = x + r, \text{ and } \text{RSP} = (\pi_2, y, \rho_1, \rho_3). \\
& \quad Ch = 3: \text{ Let } \pi_3 = \pi, r_3 = r, \text{ and } \text{RSP} = (\pi_3, r_3, \rho_1, \rho_2). \\
\text{Verification:} & \quad \text{Receiving } \text{RSP}, \text{ the verifier proceeds as follows:} \\
& \quad Ch = 1: \text{ Check that } t_x \in \text{VALID \ and } C_2 = \text{COM}(t_x; \rho_2), C_3 = \text{COM}(t_x + t_r; \rho_3). \\
& \quad Ch = 2: \text{ Check that } C_1 = \text{COM}(\pi_2, M \cdot y - c; \rho_1), C_3 = \text{COM}(T_{\pi_2}(y); \rho_3). \\
& \quad Ch = 3: \text{ Check that } C_1 = \text{COM}(\pi_3, M \cdot r_3; \rho_1), C_2 = \text{COM}(T_{\pi_3}(r_3); \rho_2). \\
\end{align*}
\]

In each case, \( V \) outputs 1 if and only if all the conditions hold. Otherwise, it outputs 0.

Fig. 1: A ZKAoK for the relation \( R_{\text{abstract}} \).

The properties of the given protocol is summarized in the following lemma.

**Lemma 8.** The protocol in Figure 1 is a \( \text{sZKAoK} \) for the relation \( R_{\text{abstract}} \) with perfect completeness, soundness error 2/3, and communication cost \( \tilde{O}(L \log q) \).

In particular:

- There exists an efficient simulator that, on input \((M,c)\), outputs an accepted transcript which is statistically close to that produced by the real prover.
- There exists an efficient knowledge extractor that, on input a commitment \text{CMT} and 3 valid responses \((\text{RSP}_1, \text{RSP}_2, \text{RSP}_3)\) to all 3 possible values of the challenge \( Ch \), outputs \( x' \in \text{VALID} \) such that \( M \cdot x' = c \mod q \).

The proof of Lemma 8 employs standard simulation and extraction techniques for Stern-type protocols \([54][62]\). We defer it to Appendix 3.
5.2 Vector Decompositions and Extensions

Our constructions in the next subsections employ the Decomposition-Extension technique for Stern-type protocols, introduced by Ling et al. [62]. We formalize their technique as follows.

- Define, for any positive integer \( B \), the number \( \delta_B := \lceil \log_2 B \rceil + 1 \) and the sequence \( B_1, \ldots, B_{\delta_B} \), where \( B_j = \lceil \frac{B+2^{j-1}}{2} \rceil \) for all \( j \in [1, \delta_B] \). As noted in [62], this sequence satisfies \( \sum_{j=1}^{\delta_B} B_j = B \), and any integer in \([-B, B]\) can be expressed as a linear combination of the \( B_j \)'s with coefficients in \([-1, 0, 1]\).

- Define the following matrices for any positive integers \( m, B \):

\[
K_{m,B} = \begin{bmatrix}
B_1 \cdots B_{\delta_B} \\
B_1 \cdots B_{\delta_B} \\
\vdots \\
B_1 \cdots B_{\delta_B}
\end{bmatrix} \in \mathbb{Z}^{m \times m_{\delta_B}},
\]

and \( \tilde{K}_{m,B} = [K_{m,B}|0^{m \times 2m_{\delta_B}}] \in \mathbb{Z}^{m \times 3m_{\delta_B}} \).

- For any positive integer \( i \), denote by \( B_{3i} \) the set of all vectors in \([-1, 0, 1]^{3i} \) having exactly \( i \) coordinates equal to \( 1 \). We denote by \( \text{Ext}_{2i}(\cdot) \) the algorithm that on input vector \( w \in \{0, 1\}^i \) having exactly \( i \) coordinates equal to 1. We denote by \( \text{Ext}_{2i}(\cdot) \) the algorithm that on input vector \( w \in \{0, 1\}^i \), outputs vector \( w \in B_{2i} \); it simply appends \( i \) suitable coordinates to \( w \).

**Lemma 9 (Decomposition-Extension).** Let \( m, B \) be positive integers. Then, there exists an efficient algorithm \( \text{DecExt}_{m,B} \) that on input vector \( v \in [-B, B]^m \), outputs vector \( \tilde{v} \in B_{3m_{\delta_B}} \) such that \( \tilde{K}_{m,B} \cdot \tilde{v} = v \).

**Proof.** Let \( v = (v_1, \ldots, v_m) \), where \( v_i \in [-B, B] \) for all \( i \in [1, m] \). For each \( i \), one can efficiently find \( v_{i,1}, \ldots, v_{i,\delta_B} \in \{-1, 0, 1\} \) such that \( \sum_{j=1}^{\delta_B} B_j \cdot v_{i,j} = v_i \).

Let \( v' = (v_{1,1}, \ldots, v_{1,\delta_B}, v_{2,1}, \ldots, v_{2,\delta_B}, \ldots, v_{m,1}, \ldots, v_{m,\delta_B})^\top \in \{-1, 0, 1\}^{m_{\delta_B}} \), then \( K_{m,B} \cdot v' = v \). By appending \( 2m_{\delta_B} \) suitable coordinates to \( v' \), one can obtain a vector \( \tilde{v} \in B_{3m_{\delta_B}} \) such that \( \tilde{K}_{m,B} \cdot \tilde{v} = v \).

Additionally, for any positive integer \( i \), let \( B_{2i} \) be the set of all vectors in \([0, 1]^{2i}\) having exactly \( i \) coordinates equal to 1. We denote by \( \text{Ext}_{2i}(\cdot) \) the algorithm that on input vector \( w \in \{0, 1\}^i \), outputs vector \( w \in B_{2i} \); it simply appends \( i \) suitable coordinates to \( w \).

5.3 Proving the Consistency of Commitments

The argument system used in our protocol for signing a committed value in Section 3.3 can be summarized as follows.

**Common Input:** Matrices \( \{D_k \in \mathbb{Z}_q^{2n \times 2m}\}_{k=0}^N \); \( B \in \mathbb{Z}_q^{n \times m} \); \( G_1 \in \mathbb{Z}_q^{n \times 2m} \);

vectors \( c_n \in \mathbb{Z}_q^{2n} \); \( \{c_{k,1} \in \mathbb{Z}_q^m\}_{k=1}^N \); \( \{c_{k,2} \in \mathbb{Z}_q^{2m}\}_{k=1}^N \); \( c_{w',1} \in \mathbb{Z}_q^m \); \( c_{w',2} \in \mathbb{Z}_q^{2m} \).
Prover’s Input: \( \{m_k \in \{0, 1\}^{2m}\}_{k=1}^{N} \); \( s' \in [- (p - 1), (p - 1)]^{2m} \);
\( \{s_{k,0} \in [-B, B]^{n}, e_{k,1} \in [-B, B]^{m} \}; \) \( e_{k,2} \in [-B, B]^{2m}\); \( s_{0} \in [-B, B]^{n}, e_{0,1} \in [-B, B]^{m}; \) \( e_{0,2} \in [-B, B]^{2m} \).

Prover’s Goal: Convince the verifier in \( \text{ZK} \) that:

\[
\begin{align*}
&c_m = D_0 \cdot s' + \sum_{k=1}^{N} D_k \cdot m_k \mod q; \\
&c_{s',1} = B^T \cdot s_0 + e_{0,1} \mod q; \quad c_{s',2} = G_1^T \cdot s_0 + e_{0,2} + \lfloor q/p \rfloor \cdot s' \mod q; \quad (15) \\
&\forall k \in [N]: c_{k,1} = B^T \cdot s_{k,0} + e_{k,1}; \quad c_{k,2} = G_1^T \cdot s_{k,0} + e_{k,2} + \lfloor q/2 \rfloor \cdot m_k.
\end{align*}
\]

We will show that the above argument system can be obtained from the one in Section 5.1. We proceed in 2 steps.

**Step 1:** Transforming the linear equations in (15) into a unified equation of the form \( M \cdot x = c \mod q \), where \( x \) has infinity norm 1, and belongs to a “specially-designed” set \( \text{VALID} \).

To do so, we first form the following vectors and matrices:

\[
\begin{align*}
&x_1 = (s_0^T, e_{0,1}^T, s_{1,0}^T, e_{1,1}^T, \ldots, s_{N,0}^T, e_{N,1}^T) = [-B, B]^{(n+3m)(N+1)}; \\
&x_2 = (m_1^T, \ldots, m_N^T) = \{0, 1\}^{2mN}; \quad x_3 = s' \in [- (p - 1), (p - 1)]^{2m} \\
&c = (c_{s',1}^T, c_{s',2}^T, \ldots, c_{N,1}^T, c_{N,2}^T) \in \mathbb{Z}_q^{2n+3m(N+1)}; \\
&D = [D_1, \ldots, D_N] \in \mathbb{Z}_q^{2n \times 2mN}; \\
&P_1 = \begin{bmatrix} B^T & G_1^T \end{bmatrix} & I_{3m}; \quad Q_r = \begin{bmatrix} 0 & \frac{1}{2} I_{2m} \end{bmatrix}; \quad Q_p = \begin{bmatrix} 0 & \frac{1}{p} I_{2m} \end{bmatrix}; \\
&M_1 = \begin{bmatrix} P_1^{0} & P_1^{1} & \ldots & P_1^{N-1} \end{bmatrix} & M_2 = \begin{bmatrix} D_0 & Q_r \end{bmatrix} & M_3 = \begin{bmatrix} D & 0 \\ Q_2 & \ldots & Q_2 \end{bmatrix}.
\end{align*}
\]

We then observe that (15) can be rewritten as:

\[
M_1 \cdot x_1 + M_2 \cdot x_2 + M_3 \cdot x_3 = c \in \mathbb{Z}_q^D,
\]

where \( D = 2n + 3m(N + 1) \).

Now we employ the Decomposition-Extension technique from Section 5.2 to convert (16) into the form \( M \cdot x = c \mod q \). Specifically, if we let:

\[
\begin{align*}
&\text{DecExt}_{(n+3m)(N+1), B}(x_1) \rightarrow \hat{x}_1 \in \mathbb{B}_{3(n+3m)(N+1)\delta_B}; \\
&M_1' = M_1 \cdot \hat{K}_{(n+3m)(N+1), B} \in \mathbb{Z}_q^{D \times 3(n+3m)(N+1)\delta_B}; \\
&\text{Ext}_{2mN}(x_2) \rightarrow \hat{x}_2 \in \mathbb{B}_{2(2mN)}; \quad M_2' = [M_2 \mid 0^{D \times 2mN}] \in \mathbb{Z}_q^{D \times 4mN}; \\
&\text{DecExt}_{2m, p-1}(x_3) \rightarrow \hat{x}_3 \in \mathbb{B}_{2(2m)\delta_{p-1}}; \quad M_3' = [M_3 \cdot \hat{K}_{2m, p-1}] \in \mathbb{Z}_q^{D \times 6m\delta_{p-1}},
\end{align*}
\]

23
L = 3(n + 3m)(N + 1)δ_B + 4mN + 6mδ_{p-1}, and $M = [M'_1 | M'_2 | M'_3] \in \mathbb{Z}_q^{D \times L}$, and $x = (\hat{x}_1^T \| \hat{x}_2^T \| \hat{x}_3^T)^T$, then we will obtain the desired equation:

$$M \cdot x = c \mod q.$$ 

Define VALID as the set of all vectors $t \in \{-1, 0, 1\}^L$ of the form $t = (t_1^T \| t_2^T \| t_3^T)^T$, where $t_1 \in B_{3(n+3m)(N+1)\delta_B}$, $t_2 \in B_{2(2mN)}$, and $t_3 \in B_{3(2m\delta_{p-1})}$. Note that $x \in $ VALID.

**Step 2:** Specifying the set $S$ and permutations of $L$ elements $\{T_\pi : \pi \in S\}$ for which the equivalence (14) holds.

- Define $S := S_{3(n+3m)(N+1)\delta_B} \times S_{4mN} \times S_{6m\delta_{p-1}}$.
- For $\pi = (\pi_1, \pi_2, \pi_3) \in S$, and for $w = (w_1^T \| w_2^T \| w_3^T)^T \in \mathbb{Z}_q^L$, where $w_1 \in \mathbb{Z}_q^{3(n+3m)(N+1)\delta_B}$, $w_2 \in \mathbb{Z}_q^{4mN}$, $w_3 \in \mathbb{Z}_q^{6m\delta_{p-1}}$, we define:

$$T_\pi = (\pi_1(w_1)^T \| \pi_2(w_2)^T \| \pi_3(w_3)^T)^T.$$

By inspection, it can be seen that the property (14) is satisfied, as desired. As a result, we can obtain the required argument system by running the protocol in Section 5.1 with common input $(P, v)$ and prover’s input $x$.

### 5.4 Proving the Possession of a Signature on a Committed Value

We now describe how to derive the protocol for proving the possession of a signature on a committed value, that is used in Section 3.3

**Common Input:** Matrices $A, \{A_j\}_{j=0}^\ell, D \in \mathbb{Z}_q^{n \times m}$; $\{E_k\}_{k=0}^N \in \mathbb{Z}_q^{2m \times 2m}$; $B \in \mathbb{Z}_q^{m \times m}$; $G_1 \in \mathbb{Z}_q^{n \times 2m}$; $G_0 \in \mathbb{Z}_q^{n \times \ell}$; vectors $c_{r,1}, \{c_{k,1}\}_{k=1}^N, c_{v,1}, c_{v,2}, c_{s,1} \in \mathbb{Z}_q^{m}$; $c_{v,2} \in \mathbb{Z}_q^{N}$; $c_{v,2} \in \mathbb{Z}_q^{2m}$; $c_{v,2} \in \mathbb{Z}_q^{2m}$; $c_{v,2} \in \mathbb{Z}_q^{2m}$; $u \in \mathbb{Z}_q^{n}$.

**Prover’s Input:** $\tau \in \{0, 1\}^\ell$; $v_1, v_2 \in [-\beta, \beta]^{m}$; $s \in \{-(p - 1), (p - 1)\}^{2m}$; $m = (m_0^T \| \ldots \| m_N^T) \in \{\{0, 1\}^{2mN}\}; \{s_{k,0}\}_{k=1}^N, s_{v,1}, s_{v,2}, s_{0}, s_{r} \in [-B, B]^m$; $\{e_{k,1}\}_{k=1}^N, e_{v,1}, e_{v,2}, e_{0,1}, e_{r,1} \in [-B, B]^m$; $\{e_{k,2}\}_{k=1}^N, e_{0,2} \in [-B, B]^m$; $e_{v,1}, e_{v,2} \in [-B, B]^m$; $e_{r,2} \in [-B, B]^m$.

**Prover’s Goal:** Convince the verifier in ZK that:

$$A \cdot v_1 + A_0 \cdot v_2 + \sum_{i=1}^\ell A_i \cdot \tau[i]v_2 - D \cdot \text{bin}(D_0 \cdot s + \sum_{k=1}^N D_k \cdot m_k) = u \mod q,$$ (17)

and that

\[
\begin{align*}
\forall k & \in [N]: c_{k,1} = B^T \cdot s_{k,0} + e_{k,1}; \quad c_{k,2} = G_1^T \cdot s_{k,0} + e_{k,2} + \frac{q}{2} \cdot m_k; \\
c_{v,1} & = B^T \cdot s_{v,1} + e_{v,1,1} \mod q; \quad c_{v,2} = G_1^T \cdot s_{v,1} + e_{v,2,1} + \frac{q}{p} \cdot v_1 \mod q; \\
c_{v,2} & = B^T \cdot s_{v,2} + e_{v,2,2} \mod q; \quad c_{v,2} = G_1^T \cdot s_{v,2} + e_{v,2,2} + \frac{q}{p} \cdot v_2 \mod q; \\
c_{s,1} & = B^T \cdot s_{s,0} + e_{s,1} \mod q; \quad c_{s,2} = G_1^T \cdot s_{s,0} + e_{s,2} + \frac{q}{p} \cdot s \mod q; \\
c_{r,1} & = B^T \cdot s_{r,1} + e_{r,1,1} \mod q; \quad c_{r,2} = G_1^T \cdot s_{r,1} + e_{r,2,2} + \frac{q}{2} \cdot \tau \mod q.
\end{align*}
\]
We proceed in 2 steps.

**Step 1:** Transforming the linear equations in (17) and (18) into a unified equation of the form \( M \cdot x = c \mod q \), where \( x \) has infinity norm 1, and belongs to a “specially-designed” set \( \text{VALID} \).

Note that, if we let \( y = \binom{D_0 \cdot s + \sum_{k=1}^N D_i \cdot m_k}{0} \in \{0, 1\}^m \), then (17) can be equivalently written as:

\[
\begin{align*}
\begin{pmatrix} A & 0 \end{pmatrix} \cdot v_1 + \begin{pmatrix} A_0 & 0 \end{pmatrix} \cdot v_2 + \sum_{i=1}^\ell \begin{pmatrix} A_i & 0 \end{pmatrix} \cdot \tau[i] v_2 + \begin{pmatrix} 0 & D_0 \end{pmatrix} \cdot s + \begin{pmatrix} -D & H_{2n \times m} \end{pmatrix} \cdot y \\
+ \begin{pmatrix} D_1 | \ldots | D_N \end{pmatrix} \cdot m &= \begin{pmatrix} u \end{pmatrix}_{0^n} \mod q.
\end{align*}
\]

Next, we use basic linear algebra to combine this equation and (18) into:

\[
F \cdot v_1 + F_0 \cdot v_2 + \sum_{i=1}^\ell F_i \cdot \tau[i] v_2 + M_1 \cdot \tau + M_2 v_1 + M_3 \cdot s = c \mod q, \quad (19)
\]

where matrices \( F, F_0, F_1, \ldots, F_\ell \in \mathbb{Z}_q^{D \times \ell}, M_1 \in \mathbb{Z}_q^{D \times (m+2mN)}, M_2 \in \mathbb{Z}_q^{D \times 3}, M_3 \in \mathbb{Z}_q^{D \times 2m} \) and vector \( c \in \mathbb{Z}_q^3 \) are built from the public input, for \( D = \ell + 3n + 8m + 3mN \).

Now we further transform (19) using the Decomposition-Extension technique. Specifically, we form the following:

\[
\begin{align*}
\text{DecExt}_{m, \beta}(v_1) &\rightarrow \hat{v}_1 \in B_{3m \delta_0}^\beta; \quad \text{DecExt}_{m, \beta}(v_2) \rightarrow \hat{v}_2 \in B_{3m \delta_0}^\beta; \\
F' &= [F \cdot \hat{K}_{m, \beta} | F_0 \cdot \hat{K}_{m, \beta} | F_1 \cdot \hat{K}_{m, \beta} | \ldots | F_\ell \cdot \hat{K}_{m, \beta} | 0^{D \times 3m \delta_0 \ell}] \in \mathbb{Z}_q^{D \times 3m \delta_0 (2\ell + 2)}; \\
\text{Ext}_{2\ell}(\tau) &\rightarrow \hat{\tau} = [\tau[1], \ldots, \tau[\ell], \ldots, \tau[2\ell]]^T \in B_{2\ell}; \quad M'_1 = [M_1 | 0_{D \times \ell}] \in B_{q^{D \times 2\ell}}; \\
\text{Ext}_{2(m+2mN)}(y) &\rightarrow \hat{y} = [y]_m \in B_{2(m+2mN)}^\beta; \quad M'_2 = [M_2 | 0_{D \times (m+2mN)}] \in \mathbb{Z}_q^{D \times 2(m+2mN)}; \\
\text{DecExt}_{2m, \beta-1}(s) &\rightarrow \hat{s} = \hat{s} \in B_{3m \delta_{\beta-1}}^\beta; \quad M'_3 = M_3 \cdot \hat{K}_{2m, B} \in \mathbb{Z}_q^{D \times 6m \delta_{\beta-1}}.
\end{align*}
\]

Now, let \( L = 3m \delta_0 (2\ell + 2) + 2\ell + 2(m + 2mN) + 6m \delta_{\beta-1} \) and construct matrix \( M' = [F' | M'_1 | M'_2] \in \mathbb{Z}_q^{D \times L} \) and vector

\[
\begin{align*}
\hat{x} &= (\hat{v}_1^T \| \hat{v}_2^T \| \tau[1] \hat{v}_2^T \| \ldots \| \tau[\ell] \hat{v}_2^T \| \ldots \| \tau[2\ell] \hat{v}_2^T \| \hat{\tau}^T \| t^T \| \hat{s}^T)^T,
\end{align*}
\]

then we will obtain the equation \( M \cdot x = c \mod q \).

Before going to Step 2, we define \( \text{VALID} \) as the set of all vectors \( w \in \{-1, 0, 1\}^L \) having the form:

\[
w = (w_1^T \| w_2^T \| g_1 w_2^T \| \ldots \| g_{2\ell} w_2^T \| g^T \| w_3^T \| w_4^T)^T
\]

for some \( w_1, w_2 \in B_{3m \delta_0}, g = (g_1, \ldots, g_{2\ell}) \in B_{2\ell}, w_3 \in B_{2(m+2mN)}, \) and \( w_4 \in B_{3(2m \delta_{\beta-1})} \). It can be checked that the constructed above vector \( x \) is an element of \( \text{VALID} \).

**Step 2:** Specifying the set \( S \) and permutations of \( L \) elements \( \{T_x : \pi \in S\} \) for which the equivalence (14) holds.
where matrices

\[
S = S_{3m|3} \times S_{3m|3} \times S_{2\ell} \times S_{2(m+2mN)} \times S_{6m|3p-1}.
\]

For \( \pi = (\phi, \psi, \gamma, \rho, \eta) \in S \) and for \( z = (z_2||z_3|| \ldots |z_{2\ell}||z_3||z_2) \in \mathbb{Z}_q^L, \) where \( w, w_1, \ldots, w_{2\ell} \in \mathbb{Z}_q^{3m|3}, \ w \in \mathbb{Z}_q^{2|2}, \ w \in \mathbb{Z}_q^{2(m+2mN)}, \ w \in \mathbb{Z}_q^{6m|3p-1}, \) we define:

\[
\pi(z) = (\phi(z)^{\top} \| \psi(z)^{\top} \| \psi(z_2)^{\top} \| \ldots \| \psi(z_{2\ell})^{\top} \| \gamma(z)^{\top} \| \rho(z)^{\top} \| \eta(z)^{\top} )^{\top}
\]

as the permutation that transforms \( z \) as follows:

1. It rearranges the order of the \( 2\ell \) blocks \( z_1, \ldots, z_{2\ell} \) according to \( \gamma. \)
2. It then permutes block \( z \) according to \( \phi, \) blocks \( z_2 \) according to \( \psi, \) block \( z_3 \) according to \( \gamma, \) block \( z \) according to \( \rho, \) and block \( z_3 \) according to \( \eta. \)

It can be check that the equivalence \([14]\) holds. Therefore, we can obtain a \( \text{sZKAoK} \) for the given relation by running the protocol in Section 5.1.

### 5.5 The Underlying ZKAoK for the Group Signature Scheme

The argument system upon which our group signature scheme is built can be summarized as follows.

**Common Input:** Matrices \( A, A_0, A_1, \ldots, A_\ell, B \in \mathbb{Z}_q^{n\times m}, D_0, D_1 \in \mathbb{Z}_q^{2n\times 2m}, \)
\( F \in \mathbb{Z}_q^{2n\times 4m}, H_{2n\times m} \in \mathbb{Z}_q^{2n\times m}, H_{4n\times 2m} \in \mathbb{Z}_q^{4n\times 2m}, G_0 \in \mathbb{Z}_q^{n\times 2m}; \) vectors \( u \in \mathbb{Z}_q^n, c_1 \in \mathbb{Z}_q^m, c_2 \in \mathbb{Z}_q^m. \)

**Prover’s Input:** \( z \in [-\beta, \beta]^{4m}, y \in \{0, 1\}^{2m}, w \in \{0, 1\}^m, d_1, d_2 \in [-\beta, \beta]^m, \)
\( s \in [-\beta, \beta]^2m, \) \( \text{id} = [\text{id}[1] \ldots \text{id}[\ell]]^T \in \{0, 1\}^\ell, \)
\( e_0 \in [-B, B]^n, e_1 \in [-B, B]^m, e_2 \in [-B, B]^{2m}. \)

**Prover’s Goal:** Convince the verifier in ZK that

\[
\begin{align*}
F \cdot z &= H_{4n\times 2m} \cdot y \mod q; \\
H_{2n\times m} \cdot w &= D_0 \cdot y + D_1 \cdot s \mod q; \\
A \cdot d_1 + A_0 \cdot d_2 + \sum_{j=1}^{\ell} A_j \cdot (\text{id}[j] \cdot d_2) - D \cdot w &= u \mod q; \\
c_1 &= B^T \cdot e_0 + e_1 \mod q; \\
c_2 &= G_0^T \cdot e_0 + e_2 + [q/2] \cdot y \mod q.
\end{align*}
\]

Using the same strategy as in Sections 5.3 and 5.4 we can derive a \( \text{sZKAoK} \) for the above relation from the protocol given in Section 5.1. As the transformations are very similar to the ones in Section 5.4 we will only sketch main points below.

In the first step, we unify the given equations to an equation of the form:

\[
V \cdot \begin{pmatrix}
    d_1 \\
    s \\
    z
\end{pmatrix} + V_0 \cdot d_2 + \sum_{j=1}^{\ell} V_j (\text{id}[j] \cdot d_2) + M_1 \cdot \begin{pmatrix}
    w \\
    y
\end{pmatrix} + M_2 \cdot \begin{pmatrix}
    e_0 \\
    e_1 \\
    e_2
\end{pmatrix} = c \mod q,
\]

where matrices \( V, V_0, \ldots, V_\ell, M_1, M_2 \) and vector \( c \) are constructed from the public input. We then perform the Decomposition-Extension technique for the secret vectors \( x_1 = (d_1^T \| s^T \| z^T)^T \in [-\beta, \beta]^{7m}, d_2 \in [-\beta, \beta]^m; x_2 \in \{0, 1\}^{3m}; \) and \( x_3 = (e_0^T \| e_1^T \| e_2^T)^T \in [-B, B]^{n+3m}. \) This allows us to obtain a unified equation \( P \cdot x = c \mod q, \) and to define the sets \( \text{VALID}, S, \) and permutations \( \{T_\pi : \pi \in S\} \) so that the equivalence \([14]\) holds, in a similar manner as in Section 5.4.

A Model for Group Signatures with Dynamic Groups

In this appendix the definition of group signatures, and the security requirements are presented, based on the Kiayias and Yung [57] model.

Informally, a group signature is a scheme that allows a group member to attest that a message was provided by a member of a group without being altered during the process and preserving the anonymity of the users. This primitive was
introduced by Bellare, Micciancio and Warinschi [11] in 2003 and was extended to dynamic groups by Bellare, Shi and Zhang (BSZ) in 2005 [13].

In the setting of dynamic groups, the syntax of group signatures includes an interactive protocol which allows users to register as new members of the group at any time. The syntax and the security model are those defined by Kiayias and Yung [57]. Like the very similar BSZ model [13], the Kiayias-Yung (KY) model assumes an interactive join protocol whereby a prospective user becomes a group member by interacting with the group manager. This protocol provides the user with a membership certificate, certᵢ, and a membership secret, secᵢ.

We denote by \( N \in \text{Poly}(n) \) the maximal number of group members.

**Definition 4 (Dynamic Group Signature).** A dynamic group signature scheme consists of the following algorithms or protocols.

**Setup**\((1^n, N)\): given a security parameter \( n \) and a maximal number of group members \( N \in \mathbb{N} \), this algorithm is run by a trusted party to generate a group public key \( Y \), the group manager’s private key \( S_{GM} \) and the opening authority’s private key \( S_{OA} \). Each key is given to the appropriate authority while \( Y \) is made public. The algorithm also initializes a public state \( St \) comprising a set data structure \( St_{users} = \emptyset \) and a string data structure \( St_{trans} = \epsilon \).

In the following, all algorithms have access to the public parameters \( Y \).

**Join**: is an interactive protocol between the group manager \( GM \) and a user \( U_i \) where the latter becomes a group member. The protocol involves two interactive Turing machines \( J_{user} \) and \( J_{GM} \) that both take \( Y \) as input. The execution, denoted as \([J_{user}(n, Y), J_{GM}(n, St, Y, S_{GM})]\), ends with user \( U_i \) obtaining a membership secret \( secᵢ \), that no one else knows, and a membership certificate \( certᵢ \). If the protocol is successful, the group manager updates the public state \( St \) by setting \( St_{users} := St_{users} \cup \{i\} \) as well as \( St_{trans} := St_{trans} || \langle i, transcriptᵢ \rangle \).

**Sign**\((certᵢ, secᵢ, M)\): given a membership certificate \( certᵢ \), a membership secret \( secᵢ \) and a message \( M \), this probabilistic algorithm outputs a signature \( σ \).

**Verify**\((σ, M)\): given a signature \( σ \), a message \( M \) and a group public key \( Y \), this deterministic algorithm returns either \( 0 \) or \( 1 \).

**Open**\((S_{OA}, M, σ)\): takes as input a message \( M \), a valid signature \( σ \) w.r.t. \( Y \), the opening authority’s private key \( S_{OA} \) and the public state \( St \). It outputs \( i \in St_{users} \cup \{⊥\} \), which is the identity of a group member or a symbol indicating an opening failure.

Each membership certificate contains a unique tag that identifies the user.

The correctness requirement basically captures that, if all parties honestly run the protocols, all algorithms are correct with respect to their specification described as above.

The Kiayias-Yung model [57] considers three security notions: the security against misidentification attacks requires that, even if the adversary can introduce users under its control in the group, it cannot produce a signature that traces outside the set of dishonest users. The notion of security against framing attacks implies that honest users can never be accused of having signed messages that
they did not sign, even if the whole system conspired against them. And finally the anonymity property is also formalized by granting the adversary access to a signature opening oracle as in the models of [13].

Correctness for Dynamic Group Signatures. Following the Kiayias-Yung terminology [57], we say that a public state $S_t$ is valid if it can be reached from $S_0 = (\emptyset, \varepsilon)$ by a Turing machine having oracle access to $J_{GM}$. Also, a state $S_{t'}$ is said to extend another state $S_t$ if it is within reach from $S_t$.

Moreover, as in [57], when we write $\text{cert}_i \equiv \gamma \text{sec}_i$, it means that there exists coin tosses $\varpi$ for $J_{GM}$ and $J_{user}$ such that, for some valid public state $S_{t'}$, the execution of the interactive protocol $[J_{user}(n, Y), J_{GM}(n, S_{t'}, Y, S_{GM})](\varpi)$ provides $J_{user}$ with $\langle i, \text{sec}_i, \text{cert}_i \rangle$.

Definition 5 (Correctness). A dynamic group signature scheme is correct if the following conditions are all satisfied:

1. In a valid state $S_t$, $|S_{t\text{users}}| = |S_{t\text{trans}}|$ always holds and two distinct entries of $S_{t\text{trans}}$ always contain certificates with distinct tag.

2. If $[J_{user}(n, Y), J_{GM}(n, S_t, Y, S_{GM})]$ is run by two honest parties following the protocol and at the end $\langle i, \text{cert}_i, \text{sec}_i \rangle$ is obtained by $J_{user}$, then it holds that $\text{cert}_i \equiv \gamma \text{sec}_i$.

3. For each $\langle i, \text{cert}_i, \text{sec}_i \rangle$ such that $\text{cert}_i = \gamma \text{sec}_i$, satisfying condition 2, it always holds that:

   $$\text{Verify}(\text{Sign}(Y, \text{cert}_i, \text{sec}_i, M), M, Y) = 1$$

4. For any outcome $\langle i, \text{cert}_i, \text{sec}_i \rangle$ of the interaction $[J_{user}(..,.), J_{GM}(.., S_t,..)]$ for some valid state $S_t$, if $\sigma = \text{Sign}(Y, \text{cert}_i, \text{sec}_i, M)$, then

   $$\text{Open}(M, \sigma, S_{OA}, Y, S_{t'}) = i.$$
When mounting attacks, adversaries will be granted access to the following oracles:

- $Q_{\text{pub}}$, $Q_{\text{keyGM}}$ and $Q_{\text{keyOA}}$: when these oracles are invoked, the interface looks up $\text{state}_I$ and returns the group public key $Y$, the GM’s private key $S_{\text{GM}}$ and the opening authority’s private key $S_{\text{OA}}$ respectively.

- $Q_{\text{a-join}}$: allows the adversary to introduce users under his control in the group. On behalf of the GM, the interface runs $J_{\text{GM}}$ in interaction with the $J_{\text{user}}$-executing adversary who plays the role of the prospective user in the join protocol. If this protocol successfully ends, the interface increments $n$, updates $St_{\text{trans}} := St_{\text{trans}} \parallel (n, \text{transcript}_n)$. It also stores the membership certificate $\text{cert}_n$ and the membership secret $\text{sec}_n$ in a private part of $\text{state}_I$.

- $Q_{\text{b-join}}$: allows the adversary, acting as a corrupted group manager, to introduce new honest group members of his/her choice. The interface triggers an execution of $[J_{\text{user}}, J_{\text{GM}}]$ and runs $J_{\text{user}}$ in interaction with the adversary who runs $J_{\text{GM}}$. If the protocol successfully completes, the interface increments $n$, adds user $n$ to $St_{\text{users}}$ and $U^b$ and sets $St_{\text{trans}} := St_{\text{trans}} \parallel (n, \text{transcript}_n)$. It stores the membership certificate $\text{cert}_n$ and the membership secret $\text{sec}_n$ in a private part of $\text{state}_I$.

- $Q_{\text{sig}}$: given a message $M$, an index $i$, the interface checks whether the private area of $\text{state}_I$ contains a certificate $\text{cert}_i$ and a membership secret $\text{sec}_i$. If no such elements ($\text{cert}_i, \text{sec}_i$) exist or if $i \notin U^b$, the interface returns $\bot$. Otherwise, it outputs a signature $\sigma$ on behalf of user $i$ and also sets $\text{Sigs} \leftarrow \text{Sigs} \parallel (i, M, \sigma)$.

- $Q_{\text{open}}$: when this oracle is invoked on input of a valid pair $(M, \sigma)$, the interface runs algorithm $\text{Open}$ using the current state $St$. When $S$ is a set of pairs of the form $(M, \sigma)$, $Q_{\text{open}}$ denotes a restricted oracle that only applies the opening algorithm to pairs $(M, \sigma)$ which are not in $S$.

- $Q_{\text{read}}$ and $Q_{\text{write}}$: are used by the adversary to read and write the content of $\text{state}_I$. Namely, at each invocation, $Q_{\text{read}}$ outputs the whole $\text{state}_I$ but the public/private keys and the private part of $\text{state}_I$ where membership secrets are stored after $Q_{\text{b-join}}$-queries. By using $Q_{\text{write}}$, the adversary can modify $\text{state}_I$ at will as long as it does not remove or alter elements of $St_{\text{users}}$, $St_{\text{trans}}$ or invalidate the public state $St$: for example, the adversary is allowed to create dummy users as long as he/she does not re-use already existing certificate tags.

Using this formalism, we can now properly define the three announced security properties:

**Security Against Misidentification Attacks.** In a misidentification attack, the adversary can corrupt the opening authority using the $Q_{\text{keyOA}}$ oracle. Moreover, he/she can also introduce malicious users in the group via $Q_{\text{a-join}}$-queries. His/her purpose is to come up with a valid signature $\sigma^*$. He/she succeeds if the produced signature $\sigma^*$ does not open to any adversarially-controlled.
Definition 6. A dynamic group signature scheme is secure against misidentification attacks if, for any PPT adversary $A$ involved in the experiment hereunder, we have the advantage of $A$ to be:

$$\text{Adv}^{\text{mis-id}}_A(n) = \Pr\left[\text{Exp}^{\text{mis-id}}_A(n) = 1\right] \in \text{negl}(n)$$

Algorithm 1: Experiment $\text{Exp}^{\text{mis-id}}_A(n)$

1. $\text{state}_A = (St, Y, \mathcal{S}_GM, \mathcal{S}_OA) \leftarrow \text{Setup}(n, N)$;
2. $(M^*, \sigma^*) \leftarrow A(Q_{\text{pub}}, Q_{\text{b-join}}, Q_{\text{read}}, Q_{\text{keyOA}})$;
3. if $\text{Verify}(\sigma^*, M^*, Y) = 0$ then
   4. return 0;
5. $i = \text{Open}(M^*, \sigma^*, \mathcal{S}_OA, Y, St')$;
6. if $i \notin U$ then
   7. return 1;
8. return 0;

Non-Frameability. Framing attacks consider the situation where the entire system, including the group manager and the opening authority, is colluding against some honest user. The adversary can corrupt the group manager as well as the opening authority (via oracles $Q_{\text{keyGM}}$ and $Q_{\text{keyOA}}$, respectively). He/she is also allowed to introduce honest group members (via $Q_{\text{b-join}}$-queries), observe the system while these users sign messages and create dummy users using $Q_{\text{write}}$. The adversary eventually aims at framing an honest group member.

Definition 7. A dynamic group signature scheme is secure against framing attacks if, for any PPT adversary $A$ involved in the experiment below, it holds that:

$$\text{Adv}^{\text{fra}}_A(n) = \Pr\left[\text{Exp}^{\text{fra}}_A(n) = 1\right] \in \text{negl}(n)$$

Full Anonymity. The notion of anonymity is formalized by means of a game involving a two-stage adversary. The first stage is called play stage and allows the adversary $A$ to modify $\text{state}_A$ via $Q_{\text{write}}$-queries and open arbitrary signatures by probing $Q_{\text{open}}$. When the play stage ends, $A$ chooses a message $M^*$ as well as two pairs $(\text{sec}^*_0, \text{cert}^*_0)$ and $(\text{sec}^*_1, \text{cert}^*_1)$, consisting of a valid membership certificate and a corresponding membership secret. Then, the challenger flips a coin $d \leftarrow \{0, 1\}$ and computes a challenge signature $\sigma^*$ using $(\text{sec}^*_d, \text{cert}^*_d)$. The adversary is given $\sigma^*$ with the task of eventually guessing the bit $d \in \{0, 1\}$. Before doing so, he/she is allowed further oracle queries throughout the second stage, called guess stage, but is restricted not to query $Q_{\text{open}}$ for $(M^*, \sigma^*)$. 

34
Algorithm 2: Experiment $\text{Exp}^{\text{fra}}_A(n)$

1. state$_I = (\text{St}, Y, \text{SGM}, \text{SOA}) \leftarrow \text{Setup}(n, N)$;
2. $(M^*, \sigma^*) \leftarrow A(Q_{\text{pub}}, Q_{\text{keyGM}}, Q_{\text{keyOA}}, Q_{\text{b-join}}, Q_{\text{sig}}, Q_{\text{read}}, Q_{\text{write}})$;
3. if $\text{Verify}(\sigma^*, M^*, Y) = 0$ then
   return 0;
4. if $i = \text{Open}(M^*, \sigma^*, \text{SOA}, Y, \text{St}') \notin U^b$ then
   return 0;
5. if $(\forall j \in U^b \text{ s.t. } j = i \text{ for } (j, M^*, \cdot) \notin \text{Sigs})$ then
   return 1;
6. return 0;

Definition 8. A dynamic group signature scheme is fully anonymous if, for any PPT adversary $A$,

$$\text{Adv}_{A}^{\text{anon}}(n) := |\Pr[\text{Exp}^{\text{anon}}_A(n) = 1] - 1/2| \in \text{negl}(n)$$

Algorithm 3: Experiment $\text{Exp}^{\text{anon}}_A(n)$

1. state$_I = (\text{St}, Y, \text{SGM}, \text{SOA}) \leftarrow \text{Setup}(n)$;
2. $(\text{aux}, M^*, (\text{sec}_0^*, \text{cert}_0^*), (\text{sec}_1^*, \text{cert}_1^*)) \leftarrow A(\text{play}; Q_{\text{pub}}, Q_{\text{keyGM}}, Q_{\text{open}}, Q_{\text{read}}, Q_{\text{write}})$;
3. if $(\neg(\text{cert}_b^* \equiv Y \text{ sec}_b^*)) \text{ for } b \in \{0, 1\}$ then
   return 0;
4. if $\text{cert}_0^* = \text{cert}_1^*$ then
   return 0;
5. Picks random $d \leftarrow \{0, 1\}$; $\sigma^* \leftarrow \text{Sign}(Y, \text{cert}_0^*, \text{sec}_0^*, M^*)$;
6. $d' \leftarrow A(\text{guess}; \sigma^*, \text{aux}, Q_{\text{pub}}, Q_{\text{keyGM}}, Q_{\text{open}}((M^*, \cdot)), Q_{\text{read}}, Q_{\text{write}})$;
7. if $d' = d$ then
   return 1;
8. return 0;

One can wonder why the revocation is not in the dynamic group signature scheme description, the reason is only pragmatic. It is a different problem to build a scheme that allows to revoke a group member than a scheme that allows inserting a group member [42], and it has to be done in a case-by-case fashion.

B  Deferred Proofs for the Signature with Efficient Protocols

In the security proof of the signature with efficient protocols, we make use of the Rényi divergence in a similar way to [7] in the proof of Theorem 2.
B.1 The Rényi Divergence

Instead of the classical statistical distance we sometime use the Rényi divergence, which is a measurement of the distance between two distributions. Its use in security proofs for lattice-based systems was first considered by Bai et al. [7].

**Definition 9 (Rényi divergence).** For any two discrete distributions $P$ and $Q$ such that $\text{Supp}(P) \subseteq \text{Supp}(Q)$, and $a \in [1, +\infty[$, we define the Rényi divergence of order $a$ by:

$$R_a(P||Q) = \left( \sum_{x \in \text{Supp}(P)} \frac{P(x)^a}{Q(x)^{a-1}} \right)^{\frac{1}{a}}$$

We define the Rényi divergences of orders 1 and $+\infty$ by:

$$R_1(P||Q) = \exp \left( \sum_{x \in \text{Supp}(P)} P(x) \log \frac{P(x)}{Q(x)} \right) \text{ and } R_\infty(P||Q) = \max_{x \in \text{Supp}(P)} \frac{P(x)}{Q(x)}.$$

The divergence $R_1$ is the (exponential) of the Kullback-Leibler divergence.

We will focus on the following properties of the Rényi divergence, the proofs can be found in [60].

**Lemma 10 ([7, Le. 2.7]).** Let $a \in [1, +\infty[$. Let $P$ and $Q$ denote distributions with $\text{Supp}(P) \subseteq \text{Supp}(Q)$. Then the following properties hold:

**Log. Positivity:** $R_a(P||Q) \geq R_a(P||P) = 1$

**Data Processing Inequality:** $R_a(P^f||Q^f) \leq R_a(P||Q)$ for any function $f$, where $P^f$ denotes the distribution of $f(y)$ induced by sampling $y \leftarrow P$ (resp. $y \leftarrow Q$)

**Multiplicativity:** Assume $P$ and $Q$ are two distributions of a pair of random variables $(Y_1, Y_2)$. For $i \in \{1,2\}$, let $P_i$ (resp. $Q_i$) denote the marginal distribution of $Y_i$ under $P$ (resp. $Q$), and let $P_{2|1}(\cdot|y_1)$ (resp. $Q_{2|1}(\cdot|y_1)$) denote the conditional distribution of $Y_2$ given that $Y_1 = y_1$. Then we have:

- $R_a(P||Q) = R_a(P_1||Q_1) \cdot R_a(P_2||Q_2)$ if $Y_1$ and $Y_2$ are independent;
- $R_a(P||Q) \leq R_\infty(P_1||Q_1) \cdot \max_{y_1 \in X} R_a(P_{2|1}(\cdot|y_1)) R_a(Q_{2|1}(\cdot|y_1)).$

**Probability Preservation:** Let $A \subseteq \text{Supp}(Q)$ be an arbitrary event. If $a \in [1, +\infty[$, then $Q(A) \geq P(A)^{\frac{1}{a}} / R_a(P||Q)$. Further we have:

$$Q(A) \geq P(A) / R_\infty(P||Q)$$

**Weak Triangle Inequality:** Let $P_1, P_2, P_3$ be three distributions with $\text{Supp}(P_1) \subseteq \text{Supp}(P_2) \subseteq \text{Supp}(P_3)$. Then we have:

$$R_a(P_1||P_3) \leq \begin{cases} R_a(P_1||P_2) \cdot R_\infty(P_2||P_3), \\ R_\infty(P_1||P_2)^{\frac{1}{a}} \cdot R_a(P_2||P_3) \end{cases} \text{ if } a \in [1, +\infty[.$$

In our proofs, we mainly use the probability preservation to bound the probabilities during hybrid games where the two distribution are not statistically indistinguishable in the attacker point of view.
B.2 Proof of Lemma 6

Proof. Let \( \mathcal{A} \) be a PPT adversary that can mount a Type I attack with non-negligible success probability \( \varepsilon \). We construct a PPT algorithm \( \mathcal{B} \) that uses \( \mathcal{A} \) to break the \( \text{SI\textsubscript{S}}_{m,q,\beta'} \) assumption. It takes as input \( \mathbf{A} \in \mathbb{Z}_q^{n \times m} \) and computes \( \mathbf{v} \in \Lambda_q^+ \) with \( 0 < ||\mathbf{v}|| \leq \beta' \).

Algorithm \( \mathcal{B} \) first chooses the \( t \)-bit strings \( \tau^{(1)}, \ldots, \tau^{(Q)} \leftarrow U(\{0,1\}^t) \) to be used in signing queries. As in \( \text{[33]} \), it guesses the shortest prefix such that the string \( \tau^* \) contained in \( \mathcal{A} \)'s forgery differs from all prefixes of \( \tau^{(1)}, \ldots, \tau^{(Q)} \). To this end, \( \mathcal{B} \) chooses \( i^* \leftarrow U(\{1, \ldots, Q\}) \) and \( t^* \leftarrow U(\{1, \ldots, t\}) \) so that, with probability \( 1/(Q \cdot \ell) \), the longest common prefix between \( \tau^* \) and one of the \( \{\tau^{(i)}\}_{i=1}^Q \) is the string \( \tau^*[1] \ldots \tau^*[t^* - 1] = \tau^{(i)}[1] \ldots \tau^{(i)}[t^* - 1] \in \{0,1\}^{t^* - 1} \) comprised of the first \( (t^* - 1) \)-th bits of \( \tau^* \in \{0,1\}^t \). We define \( \tau^j \in \{0,1\}^t \) as the \( t \)-bit string \( \tau^j = \tau^*[1] \ldots \tau^*[t] \). By construction, with probability \( 1/(Q \cdot \ell) \), we have \( \tau^j \notin \{\tau^{(i)}[1], \ldots, \tau^{(i)}[t]\} \), where \( \tau^{(i)}[1] \) denotes the \( l \)-th prefix of \( \tau^{(i)} \) for each \( i \in \{1, \ldots, Q\} \).

Then, \( \mathcal{B} \) runs \( \text{TrapGen}(1^n, 1^m, q) \) to obtain \( \mathbf{C} \in \mathbb{Z}_q^{n \times m} \) and a basis \( \mathbf{T}_C \) of \( \Lambda_q^+ (\mathbf{C}) \) with \( \|\mathbf{T}_C\| \leq O(\sqrt{n \log q}) \). Then, it picks \( \ell + 1 \) matrices \( \mathbf{Q}_0, \ldots, \mathbf{Q}_\ell \in \mathbb{Z}_q^{m \times m} \), where each matrix \( \mathbf{Q}_i \) has its columns sampled independently from \( D_{\mathbb{Z}_q^m, \sigma} \). The reduction \( \mathcal{B} \) defines the matrices \( \{\mathbf{A}_j\}_j^\ell = 0 \) as

\[
\begin{align*}
\mathbf{A}_0 &= \mathbf{A} \cdot \mathbf{Q}_0 + \left( \sum_{j=1}^{t^*} \tau^*[j] \cdot \mathbf{C} \right) \\
\mathbf{A}_j &= \mathbf{A} \cdot \mathbf{Q}_j + (-1)^{\tau^*[j]} \cdot \mathbf{C}, \quad \text{for } j \in [j, t^*] \\
\mathbf{A}_j &= \mathbf{A} \cdot \mathbf{Q}_j, \quad \text{for } j \in [t^* + 1, \ell]
\end{align*}
\]

It also sets \( \mathbf{A} = \mathbf{A}^\dagger \). We note that we have

\[
\begin{align*}
\mathbf{A}_{\tau^{(i)}} &= \left[ \mathbf{A} \mathbf{A}_0 + \sum_{j=1}^{k^*} \tau^{(i)}[j] \mathbf{A}_j \right] \\
&= \left[ \mathbf{A} \right] \left[ \mathbf{A} \cdot \mathbf{Q}_0 + \sum_{j=1}^{k^*} \tau^{(i)}[j] \mathbf{Q}_j \right] + \left( \sum_{j=1}^{k^*} \tau^*[j] + (-1)^{\tau^*[j]} \tau^{(i)}[j] \right) \cdot \mathbf{C} \\
&= \left[ \mathbf{A} \right] \left[ \mathbf{A} \cdot \mathbf{Q}_0 + \sum_{j=1}^{k^*} \tau^{(i)}[j] \mathbf{Q}_j \right] + h_{\tau^{(i)}} \cdot \mathbf{C}
\end{align*}
\]

where \( h_{\tau^{(i)}} \in [1, k^*] \subset [1, \ell] \) stands for the Hamming distance between \( \tau^{(i)}[1] \) and \( \tau^{(i)}[1] \). Note that, with probability \( 1/(Q \cdot \ell) \) and since \( q > \ell \), we have \( h_{\tau^{(i)}} \neq 0 \) mod \( q \) whenever \( \tau^{(i)}[1] \neq \tau^*[1] \).

Next, \( \mathcal{B} \) picks a random short matrix \( \mathbf{R} \leftarrow \mathbb{Z}_q^{m \times m} \) which has its columns independently sampled from \( D_{\mathbb{Z}_q^m, \sigma} \) and computes

\[ \mathbf{D} = \mathbf{A} \cdot \mathbf{R}. \]

Finally, \( \mathcal{B} \) samples short vectors \( \mathbf{e}_u \in D_{\mathbb{Z}_q^m, \sigma} \) and computes the vector \( \mathbf{u} \in \mathbb{Z}_q^m \) as \( \mathbf{u} = \mathbf{A} \cdot \mathbf{e}_u \in \mathbb{Z}_q^m \). The public key

\[ \text{PK} := (\mathbf{A}, \{\mathbf{A}_j\}_j^\ell, \{\mathbf{D}_k\}_k^N, \mathbf{D}, \mathbf{u}) \]
is given to \( A \).

At the \( i \)-th signing query \( \text{Msg}^{(i)} = (m_1^{(i)}, \ldots, m_N^{(i)}) \in [\{0,1\}]^N \), \( B \) can use the trapdoor \( T_{C} \in \mathbb{Z}^{m \times m} \) to generate a signature. To do this, \( B \) first samples \( s^{(i)} \leftarrow D_{\mathbb{Z}^m, \sigma_1} \) and computes a vector \( u_M \in \mathbb{Z}^m \) as

\[
u_M = u + D \cdot \text{bin} \left( \sum_{k=1}^{N} D_k \cdot m_k^{(i)} + D_0 \cdot s^{(i)} \right) \pmod{q}.
\]

Using \( T_{C} \in \mathbb{Z}^{m \times m} \), \( B \) can then sample a short vector \( v^{(i)} \in \mathbb{Z}^{2m} \) in \( D_{\mathbb{Z}^m}(\mathbb{A}^{\bot}(\mathbb{A})) \) such that \((\tau^{(i)}, v^{(i)}, s^{(i)})\) satisfies the verification equation \( [2] \).

When \( A \) halts, it outputs a valid signature \( \text{sig}^* = (\tau^{(i)}, v^*, s^*) \) on a message \( \text{Msg}^* = (m_1^*, \ldots, m_N^*) \) with \( \|v^*\| \leq \sigma \sqrt{2m} \) and \( \|s^*\| \leq \sigma_1 \sqrt{2m} \). At this point, \( B \) aborts and declares failure if it was unfortunate in its choice of \( i^{(l)} \in \{1, \ldots, Q\} \) and \( t^{(l)} \in \{1, \ldots, \ell\} \). Otherwise, with probability \( 1/(Q \cdot \ell) \), \( B \) correctly guessed \( i^{(l)} \in \{1, \ldots, Q\} \) and \( t^{(l)} \in \{1, \ldots, \ell\} \), in which case it can solve the given \text{SIS} \) instance as follows.

If we parse \( v^* \in \mathbb{Z}^{2m} \) as \((v_1^T \mid v_2^T)^T \) with \( v_1^*, v_2^* \in \mathbb{Z}^m \), we have the equality

\[
\begin{bmatrix}
\tilde{A} & \tilde{A} \cdot (Q_0 + \sum_{j=1}^{\ell} \tau^*[j]Q_j)
\end{bmatrix} \cdot \begin{bmatrix} v_1^* \\ v_2^* \end{bmatrix}
= u + D \cdot \text{bin} \left( D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* \right) \pmod{q}
= \tilde{A} \cdot \left( e_u + R \cdot \text{bin} \left( D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* \right) \right) \pmod{q},
\]

which implies that the vector

\[
w = v_1^* + (Q_0 + \sum_{j=1}^{\ell} \tau^*[j]Q_j) \cdot v_2^* - e_u - R \cdot \text{bin} \left( D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^* \right) \in \mathbb{Z}^m
\]

is in \( A^{\bot}(\tilde{A}) \). Moreover, with overwhelming probability, this vector is non-zero since, in \( A \)'s view, the distribution of \( e_u \in \mathbb{Z}^m \) is \( D_{\mathbb{Z}^m}(\mathbb{A}) \), which ensures that \( e_u \) is statistically hidden by the syndrome \( u = \tilde{A} \cdot e_u \). Finally, the norm of \( w \) is smaller than \( \beta' = m^{3} / \sigma^2(\ell + 3) + m^{1/2} / \sigma_1 \) which yields a valid solution of the given \text{SIS}_{m,q,\beta'} \) instance with overwhelming probability. \( \square \)

### B.3 Proof of Lemma [7]

**Proof.** We prove the result using a sequence of games. For each \( i \), we denote by \( W_i \) the event that the adversary wins by outputting a Type II forgery in \textbf{Game} \( i \).

**Game 0:** This is the real game where, at the \( i \)-th signing query \( \text{Msg}^{(i)} = (m_1^{(i)}, \ldots, m_N^{(i)}) \), the adversary obtains a signature \( \text{sig}^{(i)} = (\tau^{(i)}, v^{(i)}, s^{(i)}) \) for
each $i \in \{1, \ldots, Q\}$ from the signing oracle. At the end of the game, the adversary outputs a forgery $\text{sig}^* = (\tau^*, \mathbf{v}^*, \mathbf{s}^*)$ on a message $\text{Msg}^* = (\mathbf{m}^*_1, \ldots, \mathbf{m}^*_N)$. By hypothesis, the adversary’s advantage is $\varepsilon = \Pr[W_0]$. We assume w.l.o.g. that the random $\ell$-bit strings $\tau^{(i_1)}, \ldots, \tau^{(Q)}$ are chosen at the very beginning of the game. Since $(\text{Msg}^*, \text{sig}^*)$ is a Type II forgery, there exists an index $i^* \in \{1, \ldots, Q\}$ such that $\tau^{i^*} = \tau^{(i^*)}$.

**Game 1:** This game is identical to Game 0 with the difference that the reduction aborts the experiment in the unlikely event that, in the adversary’s forgery $\text{sig}^* = (\tau^*, \mathbf{v}^*, \mathbf{s}^*)$, $\tau^*$ coincides with more than one of the random $\ell$-bit strings $\tau^{(i_1)}, \ldots, \tau^{(Q)}$ used by the challenger. If we call $F_1$ the latter event, we have $\Pr[F_1] < Q^2/2^\ell$ since we are guaranteed to have $\sim F_1$ as long as no two $\tau^{(i)}$, $\tau^{(i)}$ collide. Given that Game 1 is identical to Game 0 until $F_1$ occurs, we have $|\Pr[W_1] - \Pr[W_0]| \leq \Pr[F_1] < Q^2/2^\ell$.

**Game 2:** This game is like Game 1 with the following difference. At the outset of the game, the challenger $\mathcal{B}$ chooses a random index $i^* \leftarrow U(\{1, \ldots, Q\})$ as a guess that $\mathcal{A}$’s forgery will recycle the $\ell$-bit string $\tau^{(i^*)} \in \{0, 1\}^\ell$ of the $i^*$ th signing query. When $\mathcal{A}$ outputs its Type II forgery $\text{sig}^* = (\tau^*, \mathbf{v}^*, \mathbf{s}^*)$, the challenger aborts in the event that $\tau^{(i^*)} \neq \tau^*$ (i.e., $i^* \neq i^*$). Since the choice of $i^*$ in $\{1, \ldots, Q\}$ is independent of $\mathcal{A}$’s view, we have $\Pr[W_2] = \Pr[W_1]/Q$.

**Game 3:** In this game, we modify the key generation phase and the way to answer signing queries. First, the challenger $\mathcal{B}$ randomly picks $h_0, h_1, \ldots, h_\ell \in \mathbb{Z}_q$ subject to the constraints

$$h_0 + \sum_{j=1}^\ell \tau^{(i^*)}[j] \cdot h_j \equiv 0 \pmod{q}$$

$$h_0 + \sum_{j=1}^\ell \tau^{(i^*)}[j] \cdot h_j \neq 0 \pmod{q} \quad i \in \{1, \ldots, Q\} \setminus \{i^*\}$$

It runs $(\mathbf{C}, \mathbf{T}_\mathbf{C}) \leftarrow \text{TrapGen}(1^n, 1^m, q)$, $(\mathbf{D}_0, \mathbf{T}_{\mathbf{D}_0}) \leftarrow \text{TrapGen}(1^{2n}, 1^{2m}, q)$ so as to obtain statistically random matrices $\mathbf{C} \in \mathbb{Z}_q^{n \times m}$, $\mathbf{D}_0 \in \mathbb{Z}_q^{2n \times 2m}$ with trapdoors $\mathbf{T}_\mathbf{C} \in \mathbb{Z}_q^{m \times m}$, $\mathbf{T}_{\mathbf{D}_0} \in \mathbb{Z}_q^{2m \times 2m}$ consisting of short bases of $\Lambda^+_q(\mathbf{C})$ and $\Lambda^+_q(\mathbf{D}_0)$, respectively. Then, $\mathcal{B}$ chooses a uniformly random $\mathbf{D} \leftarrow U(\mathbb{Z}_q^{n \times m})$ and re-randomizes it using short matrices $\mathbf{S}, \mathbf{S}_0, \mathbf{S}_1, \ldots, \mathbf{S}_\ell \leftarrow \mathbb{Z}_q^{n \times m}$, which are obtained by sampling their columns from the distribution $D_{\mathbb{Z}^m, \sigma}$. Namely, from $\mathbf{D} \in \mathbb{Z}_q^{n \times m}$, $\mathcal{B}$ defines

$$\mathbf{A} = \mathbf{D} \cdot \mathbf{S}$$

$$\mathbf{A}_0 = \mathbf{D} \cdot \mathbf{S}_0 + h_0 \cdot \mathbf{C}$$

$$\mathbf{A}_j = \mathbf{D} \cdot \mathbf{S}_j + h_j \cdot \mathbf{C} \quad \forall j \in \{1, \ldots, \ell\}$$

In addition, $\mathcal{B}$ picks random matrices $\mathbf{D}_1, \ldots, \mathbf{D}_N \leftarrow U(\mathbb{Z}_q^{2n \times 2m})$ and a random vector $\mathbf{c}_M \leftarrow U(\mathbb{Z}_q^{2n})$. It samples short vectors $\mathbf{v}_1, \mathbf{v}_2 \leftarrow D_{\mathbb{Z}^m, \sigma}$ and computes
\[ u \in \mathbb{Z}_q^n \text{ as } u = A_{\tau(i)} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{bmatrix} - \mathbf{D} \cdot \text{bin}(c_M) \mod q, \]

where

\[ A_{\tau(i)} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A} \cdot \sum_{j=1}^{\ell} \tau(i)[j] \cdot \mathbf{A}_j \end{bmatrix} = \begin{bmatrix} \mathbf{D} \cdot \mathbf{S} \\ \mathbf{D} \cdot (\mathbf{S}_0 + \sum_{j=1}^{\ell} \tau(i)[j] \cdot \mathbf{S}_j) \end{bmatrix}. \]

The adversary’s signing queries are then answered as follows.

- At the \( i \)-th signing query \((m_1^{(i)}, \ldots, m_N^{(i)})\), whenever \( i \neq i^* \), we have

\[
A_{\tau(i)} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A} \cdot \sum_{j=1}^{\ell} \tau(i)[j] \cdot \mathbf{A}_j \end{bmatrix} = \begin{bmatrix} \mathbf{D} \cdot \mathbf{S} \\ \mathbf{D} \cdot (\mathbf{S}_0 + \sum_{j=1}^{\ell} \tau(i)[j] \cdot \mathbf{S}_j) + h_{\tau(i)} \cdot \mathbf{C} \end{bmatrix} \in \mathbb{Z}_q^{n \times 2m},
\]

with \( h_{\tau(i)} = h_0 + \sum_{j=1}^{\ell} \tau(i)[j] \cdot h_j \neq 0 \). This implies that \( \mathcal{B} \) can use the trapdoor \( \mathbf{T}_C \in \mathbb{Z}^{m \times m} \) to generate a signature. To this end, \( \mathcal{B} \) first samples a discrete Gaussian vector \( s^{(i)} \) and computes \( u_M \in \mathbb{Z}_q^2 \) as

\[
u_M = u + \mathbf{D} \cdot \text{bin} \left( \sum_{k=1}^{N} \mathbf{D}_k \cdot m_k^{(i)} + \mathbf{D}_0 \cdot s^{(i)} \right) \mod q.
\]

Then, using \( \mathbf{T}_C \in \mathbb{Z}^{m \times m} \), it samples a short vector \( \mathbf{v}^{(i)} \in \mathbb{Z}_q^{2m} \) in \( D_{A_k^{M}(A_{\tau(i)}) \cdot \sigma}^{u_M} \) such that \((\tau^{(i)}, \mathbf{v}^{(i)}, s^{(i)})\) satisfies \( 2 \).

- At the \( i^* \)-th signing query \((m_1^{(i*)}, \ldots, m_N^{(i*)})\), we have

\[
A_{\tau(i^*)} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A} \cdot \sum_{j=1}^{\ell} \tau(i^*)[j] \cdot \mathbf{A}_j \end{bmatrix} = \begin{bmatrix} \mathbf{D} \cdot \mathbf{S} \\ \mathbf{D} \cdot (\mathbf{S}_0 + \sum_{j=1}^{\ell} \tau(i^*)[j] \cdot \mathbf{S}_j) \end{bmatrix} \in \mathbb{Z}_q^{n \times 2m} \quad (21)
\]

due to the constraint \( h_0 + \sum_{j=1}^{\ell} \tau(i^*)[j] \cdot h_j = 0 \mod q \). To answer the query, \( \mathcal{B} \) uses the trapdoor \( \mathbf{T}_{\mathbf{D}_0} \in \mathbb{Z}_q^{2m \times 2m} \) of \( A_k^{\perp}(\mathbf{D}_0) \) to sample a short vector \( s^{(i^*)} \in D_{A_k^{\perp}(\mathbf{D}_0) \cdot \sigma_1}^{\perp}(\mathbf{D}_0) \), where \( c_M' = c_M - \sum_{k=1}^{N} \mathbf{D}_k \cdot m_k^{(i^*)} \in \mathbb{Z}_q^2 \). The obtained vector \( s^{(i^*)} \in \mathbb{Z}_q^{2m} \) thus verifies

\[
\mathbf{D}_0 \cdot s^{(i^*)} = c_M - \sum_{k=1}^{N} \mathbf{D}_k \cdot m_k^{(i^*)} \mod q, \quad (22)
\]

and \( \mathcal{A} \) receives \( \text{sig}^{(i^*)} = (\tau^{(i^*)}, \mathbf{v}^{(i^*)}, s^{(i^*)}) \), where \( \mathbf{v}^{(i^*)} = (\mathbf{v}_1^{(i^*)} \mid \mathbf{v}_2^{(i^*)})^T \). By construction, the returned signature \( \text{sig}^{(i^*)} \) satisfies

\[
A_{\tau(i^*)} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{bmatrix} = u + \mathbf{D} \cdot \text{bin}(\mathbf{D}_0 \cdot s^{(i^*)} + \sum_{k=1}^{N} \mathbf{D}_k \cdot m_k^{(i^*)}) \mod q,
\]

and the distribution of \((\tau^{(i^*)}, \mathbf{v}^{(i^*)}, s^{(i^*)})\) is statistically the same as in Game 2.
We conclude that \( \Pr[W_2] \) is negligibly far apart from \( \Pr[W_3] \) since, by the Leftover Hash Lemma (see [3, Lemma 13]), the public key \( PK \) in Game 3 is statistically close to its distribution in Game 2.

In Game 3, we claim that the challenger \( B \) can use \( A \) to solve the SIS problem by finding a short vector of \( A_q^\perp(D) \) with probability \( \Pr[W_3] \). Indeed, with probability \( \Pr[W_3] \), the adversary outputs a valid signature \( sig = (\tau^{(i)}(\cdot), v^*, s^*) \) on a message \( M_{sig} = (m_1^*, \ldots, m_N^*) \) with \( \|v^*\| \leq \sigma \sqrt{2m} \) and \( \|s^*\| \leq \sigma_1 \sqrt{2m} \). If we parse \( v^* \in \mathbb{Z}^{2m} \) as \((v_1^T, v_2^T)\) with \( v_1^*, v_2^* \in \mathbb{Z}^m \), we have the equality

\[
A_{\tau^{(i)}} \cdot \begin{bmatrix} v_1^* \\ v_2^* \\ \end{bmatrix} = u + D \cdot \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*) \mod q. \quad (23)
\]

Due to the way \( u \in \mathbb{Z}_q^n \) was defined at the outset of the game, \( B \) also knows short vectors \( v^{(i)} = (v_1^T, v_2^T) \in \mathbb{Z}^{2m} \) such that

\[
A_{\tau^{(i)}} \cdot \begin{bmatrix} v_1 \\ v_2 \\ \end{bmatrix} = u + D \cdot \text{bin}(c_M) \mod q. \quad (24)
\]

Relation \( (22) \) implies that \( c_M \neq D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^* \mod q \) by hypothesis. It follows that \( \text{bin}(c_M) - \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*) \) is a non-zero vector in \( \{-1, 0, 1\}^m \). Subtracting \( (24) \) from \( (23) \), we get

\[
A_{\tau^{(i)}} \cdot \begin{bmatrix} v_1^* - v_1 \\ v_2^* - v_1 \\ \end{bmatrix} = D \cdot (\text{bin}(c_M) - \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*)) \mod q,
\]

which implies

\[
\begin{bmatrix} D \cdot S \mid D \cdot (S_0 + \sum_{j=1}^\ell \tau^{(i)}(j) \cdot S_j) \end{bmatrix} \cdot \begin{bmatrix} v_1^* - v_1 \\ v_2^* - v_1 \\ \end{bmatrix} = D \cdot (\text{bin}(c_M) - \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*)) \mod q. \quad (25)
\]

The above implies that the vector

\[
w = S \cdot (v_1^* - v_1) + (S_0 + \sum_{j=1}^\ell \tau^{(i)}(j) \cdot S_j) \cdot (v_2^* - v_2) + \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*) - \text{bin}(c_M)
\]

is a short integer vector of \( A_q^\perp(D) \). Indeed, its norm can be bounded as \( \|w\| \leq \beta'' \sqrt{2(\ell + 2)} \sigma^2 m^{3/2} + m^{1/2} \). We argue that it is non-zero with overwhelming probability. We already observed that \( \text{bin}(D_0 \cdot s^* + \sum_{k=1}^N D_k \cdot m_k^*) - \text{bin}(c_M) \) is a
non-zero vector of \(\{-1, 0, 1\}^m\), which rules out the event that \((v_1^*, v_2^*) = (v_1, v_2)\). Hence, we can only have \(w = 0^m\) when the equality

\[
S \cdot (v_1^* - v_1) + (S_0 + \sum_{j=1}^{\ell} \tau^{(i^j)}[j] \cdot S_j) \cdot (v_2^* - v_2)
\]

\[
= \bin(c_{A_f}) - \bin(D_0 \cdot s^* + \sum_{k=1}^{N} D_k \cdot m_k^*)
\]

(26)

holds over \(Z\). However, as long as either \(v_1^* \neq v_1\) or \(v_2^* \neq v_2\), the left-hand-side member of (26) is information theoretically unpredictable since the columns of matrices \(S\) and \(\{S_j\}_{j=0}^{\ell}\) are statistically hidden in the view of \(A\). Indeed, conditionally on the public key, each column of \(S\) and \(\{S_j\}_{j=0}^{\ell}\) has at least \(n\) bits of min-entropy, as shown by, e.g., [66, Lemma 2.7].

\[\square\]

### B.4 Proof of Theorem 2

**Proof.** The proof is very similar to the proof of Theorem 1 and we will only explain the changes.

Assuming that an adversary \(A\) can prove possession of a signature on a message \((m_1^*, \ldots, m_N^*)\) which has not been blindly signed by the issuer, we outline an algorithm \(B\) that solves a SIS instance \((A, \beta)\), where \(A = [A_1 | A_2] \in U(Z_q^{n \times 2m})\) with \(A_1, A_2 \in U(Z_q^{n \times m})\).

At the outset of the game, \(B\) generates the common parameters \((A_1, A_2)\) by choosing \(B \in_R Z_q^{n \times m}\) and defining \(G_0 = B \cdot E_0 \in Z_q^{n \times \ell}\), \(G_1 = B \cdot E_1 \in Z_q^{n \times 2m}\). The short Gaussian matrices \(E_0 \in Z_m^{m \times \ell}\) and \(E_1 \in Z_m^{m \times 2m}\) are retained for later use. Also, \(B\) flips a coin \(coin \in \{0, 1, 2\}\) as a guess for the kind of attack that \(A\) will mount. If \(coin = 0\), \(B\) expects a Type I forgery, where \(A\)'s forgery involves a new \(\tau^* \in \{0, 1\}^\ell\) that was never used by the signing oracle. If \(coin = 1\), \(B\) expects \(A\) to recycle a tag \(\tau^*\) involved in some signing query in its forgery. Namely, if \(coin = 1\), \(B\) expects an attack which is either a Type II forgery or a Type III forgery. If \(coin = 2\), \(B\) rather bets that \(A\) will break the soundness of the interactive argument systems used in the signature issuing protocol or the Prove protocol. Depending on the value of \(coin \in \{0, 1, 2\}\), \(B\) generates the issuer’s public key \(PK\) and simulates \(A\)'s view in different ways.

- **If** \(coin = 0\), **\(B\)** undertakes to find a short non-zero vector of \(A_1^+\) (\(A_1\)), which in turn yields a short non-zero vector of \(A_1^+\) (\(A\)). To this end, it defines \(A = A_1\) and generates \(PK\) by computing \(\{A_j\}_{j=0}^{\ell}\) as re-randomizations of \(A \in Z_q^{n \times m}\) as in the proof of Lemma 6. This implies that \(B\) can always answer signing queries using the trapdoor \(T_C \in Z_m^{m \times m}\) of the matrix \(C\) without even knowing the messages hidden in the commitments \(c_m\) and \(\{c_{k}\}_{k=1}^{N}, c_{s^*}\). When the adversary generates a proof of possession of its own at the end of the game, \(B\) uses the matrices \(E_0 \in Z_m^{m \times \ell}\) and \(E_1 \in Z_m^{m \times 2m}\) as an extraction trapdoor to extract a plain message-signature pair \(((m_1^*, \ldots, m_N^*), (\tau^*, v^*, s^*))\) from the ciphertexts.

42
\{c_k^i\}_{k=1}^{N} = (c_{v1}^i, c_{v2}^i, c_r^i, c_s^i) \) produced by \( A \) as part of its forgery. If the extracted \( \tau^* \) is not a new tag, then \( B \) aborts. Otherwise, it can solve the given \( \text{SIS} \) instance exactly as in the proof of Lemma 6.

- If \( \text{coin} = 1 \), the proof proceeds as in the proof of Lemma 7 with one difference in Game 3. This difference is that Game 3 is no longer statistically indistinguishable from Game 2; instead, we rely on an argument based on the Rényi divergence. In Game 3, \( B \) generates \( PK \) exactly as in the proof of Lemma 7. This implies that \( B \) takes a guess \( i^* \leftarrow U(\{1, \ldots, Q\}) \) with the hope that \( A \) will choose to recycle the tag \( \tau^{(i)} \) of the \( i^* \)-th signing query (i.e., \( \tau^* = \tau^{(i^*)} \)). As in the proof of Lemma 7, \( B \) defines \( D = A_1 \in \mathbb{Z}_q^{n \times m} \) and \( A = A_1 \cdot S \) for a small-norm matrix \( S \in \mathbb{Z}^{n \times m} \) with Gaussian entries. It also “programs” the matrices \( \{A_j\}_{j=0}^{1} \) in such a way that the trapdoor precisely vanishes at the \( i^* \)-th signing query: in other words, the sum

\[
A_0 + \sum_{j=1}^{k} \tau^{(i)}[j] A_j = \tilde{A}_1 \cdot (S_0 + \sum_{j=1}^{k} \tau^{(i)}[j] \cdot S_j) + (h_0 + \sum_{j=1}^{k} \tau^{(i)}[j] \cdot h_j) \cdot C
\]

does not depend on the matrix \( C \in \mathbb{Z}_q^{n \times m} \) (of which a trapdoor \( T_C \in \mathbb{Z}_q^{m \times m} \) is known to \( B \)) when \( \tau^{(i)} = \tau^{(i^*)} \), but it does for all other tags \( \tau^{(i)} \neq \tau^{(i^*)} \). In the setup phase, \( B \) also sets up a random matrix \( D_0 \in U(\mathbb{Z}_q^{2n \times 2m}) \) which it obtains by choosing \( A' \leftarrow U(\mathbb{Z}_q^{n \times 2m}) \) to define

\[
D_0 = \begin{bmatrix} A \\ A' \end{bmatrix} \in \mathbb{Z}_q^{2n \times 2m}.
\] (27)

Then, it computes \( c_M = D_0 \cdot s_0 \in \mathbb{Z}_q^{2n} \) for a short Gaussian vector \( s_0 \leftarrow D_{\mathbb{Z}^{2n}, \sigma_0} \), which will be used in the \( i^* \)-th query. Next, it samples short vectors \( v_1, v_2 \leftarrow D_{\mathbb{Z}^{2n}, \sigma} \) to define

\[
u = A_{\tau^{(i)}} \cdot \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} - D \cdot \text{bin}(c_M) \in \mathbb{Z}_q^n.
\]

In addition, \( B \) picks extra small-norm matrices \( R_1, \ldots, R_N \leftarrow D_{\mathbb{Z}^{2m}} \), whose columns are sampled from \( D_{\mathbb{Z}^{2m}, \sigma_0} \), which are used to define randomizations of \( D_0 \) by computing \( D_k = D_0 \cdot R_k \) for each \( k \in \{1, \ldots, N\} \). The adversary is given public parameters \( \text{par} := \{B, G_0, G_1, CK\} \), where \( CK = \{D_k\}_{k=0}^{N} \), and the public key \( PK := (A, \{A_j\}_{j=0}^{1}, D, u) \).

Using \( T_C \), \( B \) can perfectly emulate the signing oracle at all queries, except the \( i^* \)-th query where the vector \( s^{(i^*)}_o \) chosen by \( B \) is sampled from a distribution that departs from \( D_{\mathbb{Z}^{2m}, \sigma_0} \). At the \( i^* \)-th query, \( B \) uses the extraction trapdoor \( E_1 \in \mathbb{Z}^{m \times 2m} \) to obtain \( s^{(i^*)}_o \in \mathbb{Z}^{2m} \) and \( \{m_k\}_{k=1}^{N} \) which form a valid opening of \( c_m \) unless the soundness of the proof system is broken (note that the latter case is addressed by the situation \( \text{coin} = 3 \)) – from the ciphertexts \( c_s^{(i)} \) and \( \{c_k\}_{k=1}^{N} \) sent by \( A \) at step 1 of the signing protocol. Then, \( B \) computes the vector \( s^{(i^*)}_o \) as

\[
s^{(i^*)}_o = s_0 - \sum_{k=1}^{N} R_k \cdot m_k^{(i^*)} - s^{(i^*)} \in \mathbb{Z}^{2m},
\] (28)
which satisfies \( c_M = \sum_{k=1}^{N} D_k \cdot m_k^{(i)} + D_0 \cdot (s^{(i)}+ s''^{(i)}) \) and allows returning \((\tau^{(i)}, v^{(i)}, s^{''(i)})\) such that \((\tau^{(i)}, v^{(i)}, s^{(i)}+ s''^{(i)})\) satisfies the verification equation of the signature scheme. Moreover, we argue that, with noticeable probability, the integer vector \( s^{(i)} = s^{(i)} + s''^{(i)} \) will be accepted by the verification algorithm since the R{\oe}nyi divergence between the simulated distribution of \( s''^{(i)} \) and its distribution in the real game will be sufficiently small. Indeed, its distribution is now that of a Gaussian vector \( \bar{D}_{\mathbb{Z}^m, \sigma_0, \mathbf{z}^i} \) centered in

\[
\mathbf{z}^i = -\sum_{k=1}^{N} R_k \cdot m_k^{(i)} - s^{(i)} \in \mathbb{Z}^m,
\]

whose norm is at most \( \|\mathbf{z}^i\|_2 \leq N\sigma(2m)^{3/2} + \sigma(2m)^{1/2} \). By choosing the standard deviation \( \sigma_0 \) to be at least \( \sigma_0 > N\sigma(2m)^{3/2} + \sigma(2m)^{1/2} \), the R{\oe}nyi divergence between the simulated distribution of \( s''^{(i)} \) (in Game 3) and its real distribution (which is the one of Game 2) can be kept constant: we have

\[
R_2(s''^{(i)}, 2\|s''^{(i)}, 3) \leq \exp \left( 2\pi \cdot \frac{\|\mathbf{z}^i\|_2^2}{\sigma_0^2} \right) \leq \exp(2\pi).
\] (29)

This ensures that, with noticeable probability, \((\tau^{(i)}, v^{(i)}, s^{(i)})\) will pass the verification test and lead \( \mathcal{A} \) to eventually output a valid forgery. So, the success probability of \( \mathcal{A} \) in Game 3 remains noticeable as (29) implies \( \Pr[W_3] \geq \Pr[W_2]^{1/2} / \exp(2\pi) \).

When \( W_3 \) occurs in Game 3, \( \mathcal{B} \) uses the matrices \((E_0, E_1)\) to extract a plain message-signature pair \(((m^*_1, \ldots, m^*_N), (\tau^*, v^*, s^*))\) from the extractable commitments \( \{c^{(i)}_k\}_{k=1}^{N}, \{c^{(i)}_k, c^{(i)}_k\}, c^*_3, c^*_4\) generated by \( \mathcal{A} \). At this point, two cases can be distinguished. First, if \( c_M \neq \sum_{k=1}^{N} D_k \cdot m^*_k + D_0 \cdot s^* \mod q \), then algorithm \( \mathcal{B} \) can find a short vector of \( A_q^+(A_1) = A_q^+(D) \) exactly as in the proof of Lemma 7. In the event that \( c_M = \sum_{k=1}^{N} D_k \cdot m^*_k + D_0 \cdot s^* \), \( \mathcal{B} \) can use the fact that the collision \( c_M = \sum_{k=1}^{N} D_k \cdot m_k^{(i)} + D_0 \cdot s^{(i)} \) allows computing

\[
\mathbf{w} = s^* - s^{(i)} + \sum_{k=1}^{N} R_k \cdot \left( m^*_k - m_k^{(i)} \right) \in \mathbb{Z}^m,
\]

which belongs to \( A_q^+(D_0) \) and has norm \( \|\mathbf{w}\|_2 \leq N\sigma(2m)^{3/2} + 4\sigma_1 m^{3/2} \). Moreover, it is non-zero with overwhelming probability. Indeed, there exists at least one \( k \in [1, N] \) such that \( m_k^{(i)} \neq m^*_k \). Let us assume w.l.o.g. that they differ in their first two bits where \( m_k^{(i)} \) contains a 0 and \( m^*_k \) contains a 1 (recall that each bit \( b \) is encoded as \((b, \bar{b})\) in both messages). This implies that \( s''^{(i)} \) (as computed in (28)) does not depend on the first column of \( R_k \) but \( \mathbf{w} \) does. Hence, given that the columns of \( R_k \) have at least \( n \) bits of min-entropy conditionally on \( D_k = D_0 \cdot R_k \), the vector \( \mathbf{w} \in \mathbb{Z}^m \) is unpredictable to the adversary.

Due to the definition of \( D_0 \in \mathbb{Z}_q^{2n \times 2m} \) in (27), we finally note that \( \mathbf{w} \in \mathbb{Z}^m \) is also a short non-zero vector of \( A_q^+(A) \).
If \( \text{coin} = 2 \), \( \mathcal{B} \) faithfully generates \( \text{par} \) and \( PK \), but it retains the extraction trapdoor \((E_0, E_1)\) associated with the dual Regev public keys \((G_0, G_1)\). Note that \( \mathcal{A} \) can break the soundness of the proof system by either: (i) Generating ciphertexts \( \{c_k\}_{k=1}^N \) and \( c_r \) that do not encrypt an opening of \( c_m \) in the signature issuing protocol; (ii) Generating ciphertexts \( \{c_k\}_{k=1}^N, c_r, c_{v_1}, c_{v_2} \) and \( c_s \) that do not encrypt a valid signature in the \text{Prove} \) protocol. In either case, the reduction \( \mathcal{B} \) is able to detect the event by decrypting dual Regev ciphertext using \((E_0, E_1)\) and create a breach in the soundness of the argument system.

It is easy to see that, since \( \text{coin} \in \{0, 1, 2\} \) is chosen independently of \( \mathcal{A} \)'s view, it turns out to be correct with probability \( 1/3 \). As a consequence, if \( \mathcal{A} \)'s advantage is non-negligible, so is \( \mathcal{B} \)'s.

\( \square \)

**B.5 Proof of Theorem 3**

*Proof.* The proof is rather straightforward and consists of a sequence of three games.

**Game 0:** This is the real game. Namely, the adversary is given common public parameters \( \text{par} \) and comes up with a public key \( PK \) of its own. The adversary can run oblivious signing protocols with honest users. At each query, the adversary chooses a user index \( i \) and triggers an execution of the signing protocol with the challenger emulating the honest users. At some point, the adversary chooses some user index \( i^* \) for which the execution of the signing protocol ended successfully. At this point, the challenger \( \mathcal{B} \) runs the real \text{Prove} \) protocol on behalf of user \( i \). At the end of the game, the adversary outputs a bit \( b' \in \{0, 1\} \). We define \( W_0 \) to be the event that \( b' = 1 \).

**Game 1:** This game is identical to Game 0 with the difference that, at each execution of the \text{Prove} \) protocol, the challenger runs the zero-knowledge simulator of the interactive proof system. The latter simulator uses either a trapdoor hidden in the common reference string (if Damgård’s technique \cite{DBLP:conf/crypto/Damgard00} is used) or proceeds by programming the random oracle which allows implementing the Fiat-Shamir heuristic. In either case, the statistical zero-knowledge property ensures that the adversary cannot distinguish Game 1 from Game 0 and \( |\Pr[W_1] - \Pr[W_0]| \in \text{negl}(\lambda) \).

**Game 2:** This game is like Game 1 except that, at each execution of the \text{Prove} \) protocol, the ciphertexts \( \{c_k\}_{k=1}^N, c_r, c_{v_1}, c_{v_2} \) encrypt random messages instead of the actual witnesses. The semantic security of the dual Regev cryptosystem ensures that, under the \text{LWE} \) assumption, the adversary is unable to see the difference. Hence, we have \( |\Pr[W_2] - \Pr[W_1]| \leq \text{Adv}_{\text{LWE}}(\lambda) \).

In Game 2, it is easy that the adversary is interacting with a simulator that emulates the user in the \text{Prove} \) protocol without using the any message-signature pair. We thus conclude that, under the \text{LWE} \) assumption, \( \mathcal{A} \)'s view cannot distinguish a real proof of signature possession from a simulated proof produced without any witness.

\( \square \)
C Security Proofs for the Dynamic Group Signature

C.1 Proof of Theorem 4

Proof. We prove that any adversary $\mathcal{A}$ with non-negligible success probability $\epsilon$ implies an algorithm $\mathcal{B}$ solving the SIS problem in the random oracle model.

Let $\mathcal{A}$ be such a PPT adversary. We build a PPT algorithm $\mathcal{B}$ that uses $\mathcal{A}$ to solve $\text{SIS}_{m,q,\beta}$: Specifically, $\mathcal{B}$ takes as input $\mathcal{A} = [\mathbf{A}_1 | \mathbf{A}_2] \in \mathbb{Z}_q^{n \times 2m}$, where $\mathbf{A}_1, \mathbf{A}_2 \in \mathbb{Z}_q^{n \times m}$, and finds $\mathbf{w} \in \Lambda_+^\perp (\mathbf{A})$ with $0 < \|\mathbf{w}\| \leq \beta$.

Initialization. Algorithm $\mathcal{B}$ first chooses a random bit $\text{coin} \leftarrow U(\{0, 1\})$ as a guess for the kind of misidentification attack that $\mathcal{A}$ will mount. Also, $\mathcal{B}$ chooses a random $\ell$-bit string $\text{id}^* \leftarrow U(\{0, 1\}^\ell)$ for which user $\mathcal{B}$'s expectation that the knowledge extractor reveals witnesses containing a new identifier $\text{id}^* \in \{0, 1\}^\ell$ that does not belong to any user in $U$. In this case, $\mathcal{B}$ will be able to exploit $\mathcal{A}$'s forgery when $\text{id}^* = \text{id}^\dagger$. The case $\text{coin} = 1$ corresponds to $\mathcal{B}$'s expectation that the knowledge extractor will obtain the identifier $\text{id}^* = \text{id}^\dagger$ of a group member in $U$ (i.e., a group member that was legitimately introduced at the $i^*$-th $Q_{\text{a-join}}$-query, for some $i^* \in \{1, \ldots, Q_n\}$, where the identifier $\text{id}^\dagger$ is used by $Q_{\text{a-join}}$), but $\text{bin}(\mathbf{v}^*) \in \{0, 1\}^{2m}$ (which is encrypted in in $\mathbf{c}^{\dagger}_q$ as part of the forgery $\Sigma^*$) and the extracted $\mathbf{s}^* \in \mathbb{Z}^{2m}$ are such that $\text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}^*) + \mathbf{D}_1 \cdot \mathbf{s}^*) \in \{0, 1\}^m$ does not match the string $\text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}^*) + \mathbf{D}_1 \cdot \mathbf{s}^*) \in \{0, 1\}^{2m}$ for which user $i^*$ obtained a membership certificate at the $i^*$-th $Q_{\text{a-join}}$-query. When $\text{coin} = 1$, the choice of $\text{id}^*$ corresponds to a guess that the knowledge extractor will reveal an $\ell$-bit identifier that coincides with the identifier $\text{id}^\dagger$ assigned to the user introduced at the $i^*$-th $Q_{\text{a-join}}$-query. The last case $\text{coin} = 2$ corresponds to $\mathcal{B}$'s expectation that decrypting $c^{\dagger}_q$ (which is part of $\Sigma^*$) and running the knowledge extractor on $\mathcal{A}$ will uncover vectors $\text{bin}(\mathbf{v}^*) \in \{0, 1\}^{2m}$, $\mathbf{w}^* \in \{0, 1\}^m$ and $\mathbf{s}^* \in \mathbb{Z}^{2m}$ such that $\mathbf{w}^* = \text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}^*) + \mathbf{D}_1 \cdot \mathbf{s}^*)$ and

$$\text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}^*) + \mathbf{D}_1 \cdot \mathbf{s}^*) = \text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}^*) + \mathbf{D}_1 \cdot \mathbf{s}^*)$$

but $(\text{bin}(\mathbf{v}^*), \mathbf{s}^*) \neq (\text{bin}(\mathbf{v}^*), \mathbf{s}^*)$, where $\mathbf{v}^* \in \mathbb{Z}_q^{4n}$ and $\mathbf{s}^* \in \mathbb{Z}^{2m}$ are the vectors involved in the $i^*$-th $Q_{\text{a-join}}$-query.

Depending on $\text{coin} \in \{0, 1, 2\}$, the group public key $\mathcal{Y}$ is generated using different methods.

- If $\text{coin} = 0$, algorithm $\mathcal{B}$ first randomly chooses $\text{id}^\dagger \leftarrow U(\{0, 1\}^\ell)$ as a guess for the $\ell$-bit string that will be revealed by the knowledge extractor of the proof system after repeated executions of the adversary $\mathcal{A}$. Then, it runs $\text{TrapGen}(\mathbb{1}^n, \mathbb{1}^m, q)$ to obtain $\mathbf{C} \in \mathbb{Z}_q^{n \times m}$ and a basis $\mathbf{T}_C$ of $\Lambda_+^\perp (\mathbf{C})$ with $\|\mathbf{T}_C\| \leq O(\sqrt{n \log q})$. Then, it chooses $\ell + 2$ matrices $\mathbf{Q}_0, \ldots, \mathbf{Q}_\ell, \mathbf{Q}_D \in \mathbb{Z}_q^{m \times m}$, each matrix having its columns sampled independently from $D_{\mathbb{Z}^m, \sigma}$. Then, $\mathcal{B}$ defines the matrices $\{\mathbf{A}_i\}_{i=0}^\ell$ as

$$\begin{align*}
\mathbf{A}_0 &= \tilde{\mathbf{A}}_1 \cdot \mathbf{Q}_0 + (\sum_{i=1}^\ell \text{id}^\dagger[i] \cdot \mathbf{C} \\
\mathbf{A}_j &= \tilde{\mathbf{A}}_1 \cdot \mathbf{Q}_j + (-1)^{\text{id}^\dagger[j]} \cdot \mathbf{C}, \quad \text{for } j \in [1, \ell] \\
\mathbf{D} &= \tilde{\mathbf{A}}_1 \cdot \mathbf{Q}_D
\end{align*}$$
It also defines $A = \bar{A}_1$. Next, it samples a vector $e_u \leftarrow D^{n \times \sigma}_U$, and computes a syndrome $u = \bar{A}_1 \cdot e_u \in \mathbb{Z}_q^n$. It picks $D_0, D_1 \leftarrow U(\mathbb{Z}_{q}^{2n \times 2m})$ at random and also faithfully generates the GPV master key pair $(B, T_B)$ as in Step 3 of the real setup algorithm. The group public key $\mathcal{Y} = (A, \{A_j\}_{j=0}^{\ell}, B, D_0, D_1, F, u, OTS, H, H_0)$ is finally given to $A$.

Note that, for each $id \neq id^\dagger$, we have

$$A_{id} = \begin{bmatrix} \bar{A}_1 & A_{0} + \sum_{i=1}^{\ell} id[i] \bar{A}_i \end{bmatrix}$$

$$= \begin{bmatrix} \bar{A}_1 & (Q_0 + \sum_{i=1}^{\ell} id[i]Q_i) + (\sum_{i=1}^{\ell} id[i] + (-1)^{id[i]}id[i]) \cdot C \end{bmatrix}$$

$$= [\bar{A}_1 \mid \bar{A}_1 + h_{id} \cdot C]$$

(31)

where $h_{id} \in [1, \ell]$ denotes the Hamming distance between the identifiers $id$ and $id^\dagger$. Since $q > \ell$, we have $h_{id} \neq 0 \mod q$ whenever $id_j \neq id^\dagger_j$, so that algorithm $B$ is able to compute (see [3] Se. 4.2), using the basis $T_C$ of $A_{q}^\perp(C)$ and the refined GPVSample of Lemma [2] a basis $T_{id}$ of $A_{q}^\perp(A_{id})$ with $\|T_{id}\| \leq \Omega(m\sqrt{\ell n \log q})$. In contrast, algorithm $B$ lacks a trapdoor for $A_{id^\dagger}$ as the latter only depends on $A$ and $\{Q_{k}\}_{k=0}^{\ell}$. Observe that, since the columns of the matrices $\{Q_{k}\}_{k=0}^{\ell}$ are sampled from $D_{\mathbb{Z}^{m \times n}}$, the matrices $A_{0}, \ldots , A_{\ell}$ are within statistical distance $2^{-\Omega(m)}$ of $U(\mathbb{Z}_{q}^{n \times m})$.

- If $coin = 1$, algorithm $B$ sets up $\mathcal{Y}$ by defining $D = \bar{A}_1$. Initially, $B$ chooses $Q_{a} \leftarrow 1$ distinct strings $id_1, \ldots , id_{\ell-1}, id_{\ell+1}, \ldots , id_{Q_{a}} \in \{0,1\}^{\ell}$ such that, for each $i \in [1, Q_{a}]\setminus \{i^*\}$, $id_i$ will be embedded in the membership certificate returned in the $i$-th $Q_{a}$-join-query. Let also $id^\dagger = id_i^*$ be the $\ell$-bit identifier that will be used in the $i^*$-th query. The reduction $B$ picks random $h_0, h_1, \ldots , h_{\ell} \in \mathbb{Z}_q$ under the constraints

$$h_{id} = h_0 + \sum_{j=1}^{\ell} id^\dagger[j] \cdot h_j \equiv 0 \mod q$$

$$h_{id_i} = h_0 + \sum_{j=1}^{\ell} id_i[j] \cdot h_j \equiv 0 \mod q \quad \forall i \in \{1, \ldots , Q_{a}\}\setminus \{i^*\}$$

Next, $B$ runs $(C, T_C) \leftarrow \text{TranGen}(1^n, 1^m, q)$, $(D_1, T_{D_1}) \leftarrow \text{TranGen}(1^{2n}, 1^{2m}, q)$ so as to obtain statistically random matrices $C \in \mathbb{Z}_{q}^{n \times m}$, $D_1 \in \mathbb{Z}_{q}^{2n \times 2m}$ together with trapdoors $T_C \in \mathbb{Z}_{q}^{m \times m}$, $T_{D_1} \in \mathbb{Z}_{q}^{2m \times 2m}$ consisting of short bases of $A_{q}^\perp(C)$ and $A_{q}^\perp(D_{1})$, respectively. Then, $B$ picks a random $D_0 \leftarrow U(\mathbb{Z}_{q}^{2n \times 2m})$ and re-randomizes $D = A_1 \in \mathbb{Z}_{q}^{n \times m}$ using Gaussian matrices $S, S_0, S_1, \ldots , S_\ell \leftarrow \mathbb{Z}_{q}^{m \times m}$ whose columns are sampled from the distribution $D_{\mathbb{Z}^{m \times n}}$. Namely, from $D = \bar{A}_1$, $B$ defines

$$A = \bar{A}_1 \cdot S$$

$$A_0 = \bar{A}_1 \cdot S_0 + h_0 \cdot C$$

$$A_j = \bar{A}_1 \cdot S_j + h_j \cdot C \quad \forall j \in \{1, \ldots , \ell\}$$
As part of the generation of $Y$, the vector $u \in \mathbb{Z}_q^n$ is obtained by picking short discrete Gaussian vectors $d_{i,1}, d_{i,2} \leftarrow D_{\mathbb{Z}_n^{m,\sigma}}$ and computing

$$u = [A \mid A_0 + \sum_{j=1}^{\ell} \text{id}_j[A_j] \cdot \begin{bmatrix} d_{i,1} \\ d_{i,2} \end{bmatrix}] - D \cdot \text{bin}(c_M),$$

where $c_M \leftarrow U(\mathbb{Z}_q^n)$ is a randomly chosen vector. Observe that, since $A$ is statistically uniform over $\mathbb{Z}_q^n$ and $d_{i,1} \leftarrow D_{\mathbb{Z}_n^{m,\sigma}}$, the distribution of $u$ is statistically close to $U(\mathbb{Z}_q^n)$.

- If $\text{coin} = 2$, $B$ picks $A' \leftarrow U(\mathbb{Z}_q^{n \times 2m})$ and a random matrix $Q \leftarrow \mathbb{Z}_q^{2m \times 2m}$ whose columns are sampled from $D_{\mathbb{Z}_n^{2m,\sigma}}$. These are used to define

$$D_0 = \begin{bmatrix} A \\ A' \end{bmatrix} \in \mathbb{Z}_q^{2n \times 2m},$$

and $D_1 = D_0 \cdot Q \mod q$, which is statistically close to $U(\mathbb{Z}_q^{2n \times 2m})$. All other components of $Y$ are obtained by faithfully running the setup algorithm.

For each value of $\text{coin} \in \{0, 1, 2\}$, the group public key

$$Y = (A, \{A_j\}_{j=0}^{\ell}, B, D, D_0, D_1, F, u, \mathcal{OTS}, H, H_0)$$

has a distribution which is statistically close to that of the real scheme and $Y$ is given to $A$.

**Queries.** The reduction $B$ starts interacting with the adversary $A$ and the way it handles $A$’s queries to the $Q_{\text{a-join}}$ oracle depends on the value of the bit $\text{coin} \in \{0, 1, 2\}$.

- If $\text{coin} = 0$, answers $Q_{\text{a-join}}$-queries as follows. When $A$ triggers an execution of the joining protocol, it chooses a syndrome $v_i \in \mathbb{Z}_q^n$. To answer the query, $B$ chooses a fresh $\ell$-bit identifier $\text{id}_i \in \{0, 1\}^\ell$ such that $\text{id}_i \neq \text{id}_i^\perp$. If $A$ also provides a correct signature $s_{\text{sig}_i}$ such that $\text{Verify}_{\text{upkt}}[v_i, s_{\text{sig}_i}] = 1$, $B$ samples $s_i \leftarrow D_{\mathbb{Z}_n^{2m,\sigma}}$ and uses the trapdoor $T_C$ to compute a short vector $d_i = [d_{i,1} \mid d_{i,2}^T]^T \in \mathbb{Z}_{2m}^2$ such that

$$A_{\text{id}_i} \cdot \begin{bmatrix} d_{i,1} \\ d_{i,2} \end{bmatrix} = u + D \cdot \text{bin}(D_0 \cdot \text{bin}(v_i) + D_1 \cdot s_i),$$

where $A_{\text{id}_i} \in \mathbb{Z}_q^{n \times 2m}$ is the matrix in $[31]$. Note that $B$ is able to compute such a vector using the $\text{SampleRight}$ algorithm of $[3]$ (since the Hamming distance $h_{\text{id}_i}$ between $\text{id}_i$ and $\text{id}_i^\perp$ non-zero). The membership certificate $\text{cert}_i = (\text{id}_i, d_i, s_i)$ is then returned to $A$.

- If $\text{coin} = 1$, algorithm $B$ responds each $Q_{\text{a-join}}$-query depending on the index $i \in \{1, \ldots, Q_a\}$ of the query. Specifically, we distinguish two cases.
- If \( i \neq i^* \), \( \mathcal{B} \) proceeds as in the previous case. Namely, it recalls the \( \ell \)-bit identifier \( \text{id}_i \in \{0,1\}^\ell \) (for which \( \text{id}_i \neq \text{id}_{i^*} \)) that was chosen in the setup phase and samples a short vector \( \text{s}_i \leftarrow D_{\mathbb{Z}^{2m, \sigma}}. \) If \( \mathcal{A} \) also provides a correct signature \( \text{sig}_i \) such that \( \text{Verify}_{\text{upk}[i]}(\text{v}_i, \text{sig}_i) = 1 \), generates a membership certificate \( \text{cert}_i \) for \( \mathcal{A} \) as in the case \( \text{coin} = 0. \) Note that

\[
\begin{align*}
\mathbf{A}_{\text{id}_i} &= \begin{bmatrix}
\tilde{A} \cdot \mathbf{S} & (S_0 + \sum_{j=1}^\ell \text{id}_i[j]S_j) + h_{\text{id}_i} \mathbf{C}
\end{bmatrix} \\
&= \begin{bmatrix}
\tilde{A} \cdot \mathbf{S} & \tilde{A} + h_{\text{id}_i} \cdot \mathbf{C}
\end{bmatrix}
\end{align*}
\]

(35)

Since \( h_{\text{id}_i} \neq 0, \mathcal{B} \) can use the trapdoor \( \mathbf{T}_C \in \mathbb{Z}^{m \times m} \) of \( A_q^\perp(C) \) to compute a short vector \( \mathbf{d}_i = [d_{i,1}^T \mid d_{i,2}^T]^T \in \mathbb{Z}^{2m} \) such that

\[
\mathbf{A}_{\text{id}_i} \cdot \begin{bmatrix} d_{i,1}^T \\ d_{i,1} \end{bmatrix} = \mathbf{u} + \mathbf{D} \cdot \text{bin}(\mathbf{D}_0 \cdot \text{bin}(\mathbf{v}_i) + \mathbf{D}_1 \cdot \mathbf{s}_i),
\]

where \( \mathbf{v}_i \in \mathbb{Z}_q^{4m} \) is the syndrome chosen by \( \mathcal{A} \) at step 1 of the joining protocol.

- If \( i = i^* \), \( \mathcal{B} \) undertakes to generate a membership certificate \( \text{cert}_{i^*} \) for the \( \ell \)-bit identifier \( \text{id}_{i^*} \in \{0,1\}^\ell \) that was chosen at the outset of the game. To this end, \( \mathcal{B} \) has to compute \( \text{cert}_{i^*} \), without using the trapdoor \( \mathbf{T}_C \) since the matrix \( \mathbf{A}_{\text{id}_{i^*}} \) does no longer depend on \( \mathbf{C} \) in (35). This can be done by recalling the vector \( \mathbf{d}_{i^*,1}, \mathbf{d}_{i^*,2} \in \mathbb{Z}^{m} \) and \( \mathbf{c}_M \in \mathbb{Z}_q^{2m} \) that were used to define \( \mathbf{u} \in \mathbb{Z}_q^4 \) in (33) and using \( \mathbf{T}_{\mathbf{D}}. \) If \( \mathcal{A} \) provides a correct signature \( \text{sig}_{i^*} \) such that \( \text{Verify}_{\text{upk}[i^*]}(\text{v}_{i^*}, \text{sig}_{i^*}) = 1 \), \( \mathcal{B} \) uses the trapdoor \( \mathbf{T}_{\mathbf{D}} \) of \( A_q^\perp(\mathbf{D}_{1^*}) \) to sample a short vector \( \mathbf{s}_{i^*} \in \mathbb{Z}^{2m} \) of \( D_{\mathbb{Z}_q^4}(\mathbf{D}_{1^*}, \sigma) \), where \( \mathbf{c}_{i^*} = \mathbf{c}_M - \mathbf{D}_0 \cdot \text{bin}(\mathbf{v}_{i^*}) \mod q, \) satisfying

\[
\mathbf{D}_1 \cdot \mathbf{s}_{i^*} = \mathbf{c}_M - \mathbf{D}_0 \cdot \text{bin}(\mathbf{v}_{i^*}) \mod q,
\]

before returning \( \text{cert}_{i^*} = ([\text{id}_{i^*}, \mathbf{d}_{i^*} = [d_{i^*,1}^T \mid d_{i^*,2}^T]^T, \mathbf{s}_{i^*}) \) to \( \mathcal{A}. \) From the definition of \( \mathbf{u} \in \mathbb{Z}_q^4 \) (33), it is easy to see that \( \text{cert}_{i^*} = ([\text{id}_{i^*}, \mathbf{d}_{i^*}, \mathbf{s}_{i^*}) \) forms a valid membership certificate for any membership secret \( \mathbf{z}_{i^*} \in \mathbb{Z}_q^{2m} \) corresponding to the syndrome \( \mathbf{v}_{i^*} = \mathbf{F} \cdot \mathbf{z}_{i^*} \mod q.

Regardless of the value of \( \text{coin}, \) queries to the random oracle \( H \) are handled by returning a uniformly chosen value in \( \{1,2,3\}^4. \) For each \( \kappa \leq Q_H, \) we let \( r_\kappa \) denote the answer to the \( \kappa \)-th \( H \)-query. Of course, if the adversary makes a given query more than once, then \( \mathcal{B} \) consistently returns the previously defined value. Queries to the random oracle \( H_0 \) are answered in the usual way, by returning a uniformly random value in the appropriate range.

**Forgery.** When \( \mathcal{A} \) halts, it outputs a signature \( \Sigma^* = (\text{VK}^*, \text{c}_x^*, \pi_K^*, \text{sig}^*) \) on some message \( M^* \). At this point, \( \mathcal{B} \) uses the trapdoor \( \mathbf{T}_B \) to decrypt \( \text{c}_x^* \) and obtain an \( m \)-bit string \( \text{bin}(\mathbf{v}^*) \in \{0,1\}^m. \)

If we parse the proof of knowledge \( \pi_K^* \) as \( \{(\text{Comm}_{K,j}^*\}_{j=1}^t, \text{Chall}_{K^*}, \{\text{Resp}_{K,j}^*\}_{j=1}^t) \), with high probability, \( \mathcal{A} \) must have invoked the random oracle \( H \) on the input \( (M^*, \text{VK}^*, \text{c}_x^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t). \) Otherwise, the probability that \( \text{Chall}_{K^*} = H(M^*, \text{VK}^*, \text{c}_x^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t) \) is negligible (at most \( 3^{-t} \)). It comes that, with
probability at least $\epsilon' := \epsilon - 3^{-t}$, the tuple $(M^*, VK^*, c_i^*, \{Comm^*_j\}_{j=1})$ coincides with the $\kappa^*$-th random oracle query for some $\kappa^* \leq Q_H$.

At this stage, the reduction $B$ runs the adversary $A$ up to $32 \cdot Q_H / (\epsilon - 3^{-t})$ times with the same random tape and input as in the initial run. All queries are answered as previously with one difference in the treatment of random oracle queries. Namely, the first $\kappa^* - 1$ random oracle queries – which are identical to those of the first execution since $A$ is run with the same random tape as before – receive the same answers $Chall_1, \ldots, Chall_{\kappa^* - 1}$ as in the first run. This implies that the $\kappa^*$-th query will involve exactly the same tuple $(M^*, VK^*, c_i^*, \{Comm^*_j\}_{j=1})$ as in the first run. However, from the $\kappa^*$-th query onwards, $A$ obtains fresh random oracle values $Chall'_1, \ldots, Chall'_Q$ at each new execution. The Improved Forking Lemma of Brickell et al. guarantees that, with probability at least $1/2$, $B$ can obtain a 3-fork involving the same tuple $(M^*, VK^*, c_i^*, \{Comm^*_j\}_{j=1})$ with pairwise distinct answers $Chall'^{(1)}_1, Chall'^{(2)}_1, Chall'^{(3)}_1 \in \{1, 2, 3\}^t$. With probability $1 - (7/9)^t$ it can be shown that there exists an index $j \in \{1, \ldots, t\}$ for which the $j$-th bits of $Chall'^{(1)}_1, Chall'^{(2)}_1, Chall'^{(3)}_1$ are $(Chall'^{(1)}_{\kappa^* - j}, Chall'^{(2)}_{\kappa^* - j}, Chall'^{(3)}_{\kappa^* - j}) = (1, 2, 3)$.

From the corresponding responses $(\text{Resp}^*_1, \text{Resp}^*_2, \text{Resp}^*_3)$, $B$ is able to extract witnesses $(d_1^*, d_2^*) \in \mathbb{Z}^m \times \mathbb{Z}^m$, $id^* \in \{0, 1\}^t$ and $w^* \in \{0, 1\}^m$ from the proof of knowledge $\pi^*_K$ such that

$$A_{id^*} \cdot \begin{bmatrix} d_1^* \\ d_2^* \end{bmatrix} = u + D \cdot w^*$$

$$w^* = \bin(D_0 \cdot (\bin(v^*) + D_1 \cdot s^*))$$

At this point, $B$ aborts and declares failure in the following situations:

- $\text{coin} = 0$ but $id^* \in \{0, 1\}^t$ is recycled from some output of the $Q_{a, join}$ oracle.
- $\text{coin} = 0$ and $id^* \neq id^1$.
- $\text{coin} = 1$ but $id^* \in \{0, 1\}^t$ never appeared in a membership certificate returned by the $Q_{a, join}$ oracle.
- $\text{coin} = 1$ and $id^* \in \{0, 1\}^t$ belongs to some user in $U^a$, but this user is not the one introduced at the $i^*$-th $Q_{a, join}$-query (i.e., $i^* \neq i^t$ and $id^* \neq id^1$).
- $\text{coin} = 1$ and the knowledge extractor revealed vectors $\bin(v^*) \in \{0, 1\}^{2m}$ and $s^* \in \mathbb{Z}^{2m}$ satisfying the collision $[30]$, where $\bin(v^*)$ and $s^*$ are the vectors involved in the $i^*$-th $Q_{a, join}$ query.
- $\text{coin} = 2$ and the knowledge extraction yields vectors $\bin(v^*) \in \{0, 1\}^{2m}$ and $s^* \in \mathbb{Z}^{2m}$ such that the collision $[30]$ does not occur.

We fail the event that one of the above situations occurs. Given that the choices of $\text{coin} \leftarrow U(\{0, 1, 2\})$ and $i^* \leftarrow U([1, Q_a])$ are completely independent of $A$’s view, the choice of $\text{coin}$ is correct with probability $1/3$. If $\text{coin} = 0$, $B$’s choice of $id^1 \leftarrow U(\{0, 1\}^t)$ is correct with probability $1/(N_{gs} - Q_a) \geq 1/N_{gs}$ and, when $\text{coin} = 1$, $B$’s correctly guesses $i^* \in [1, Q_a]$ with probability $1/Q_a$. We find

$$\Pr[\text{fail}] \geq \frac{1}{3 \cdot \max(N_{gs}, Q_a)} = \frac{1}{3 \cdot N_{gs}}.$$
Assuming that fail does not occur, \( \mathcal{B} \) can solve the problem instance as follows.

- If coin = 0, we have \( \text{id}^* = \text{id}^1 \) and \( \mathcal{B} \) knows a short vector \( e_u \in \mathbb{Z}^m \) such that \( u = A_1 \cdot e_u \mod q \). Hence, it can obtain a short integer vector

\[
\mathbf{h} = d_1^* + (Q_0 + \sum_{i=1}^\ell \text{id}^1[i]Q_i) \cdot d_2^* - Q_D \cdot \text{bin}(\mathbf{v}^*) - e_u \in \mathbb{Z}^m
\]

such that \( \hat{A}_1 \cdot \mathbf{h} = 0^m \mod q \). Moreover, we have \( \mathbf{h} \neq 0^m \) w.h.p. since the syndrome \( u \in \mathbb{Z}_q^m \) statistically hides \( e_u \in \mathbb{Z}^m \) in \( A_q^u(\hat{A}_1) \). Finally, the norm of \( \mathbf{h} \) is at most \( \|\mathbf{h}\|_2 \leq (\ell + 1)\sigma^2m^{3/2} + \sigma m^{1/2}(m + 2) \). This implies that \( (\mathbf{h}^T | 0^m)^T \) is a short non-zero vector of \( A_q^u(\hat{A}) \) and solves the initial SIS instance.

- If coin = 1, the extracted witnesses \( (d_1^*, d_2^*, s^*, \text{id}^*) \) and the decrypted \( \text{bin}(\mathbf{v}^*) \) satisfy \( \text{id}^* = \text{id}^1 \),

\[
\mathbf{w}^* = \text{bin}(D_0 \cdot \text{bin}(\mathbf{v}^*) + D_1 \cdot s^*) \neq \text{bin}(D_0 \cdot \text{bin}(v_i^*) + D_1 \cdot s_i^*) = w_i^*
\]

(since \( \neg \text{fail} \) implies that the collision \( 30 \) did not occur if \( \text{coin} = 1 \)) and

\[
[A \mid A_0 \mid A_1 \mid \ldots \mid A_\ell \mid - D] \cdot \begin{bmatrix} d_1^* \\ d_2^* \\ \text{id}^1[1]d_2^* \\ \vdots \\ \text{id}^1[\ell]d_2^* \\ w_i^* \end{bmatrix} = u \mod q. \tag{36}
\]

Since \( \mathcal{B} \) already knew short vectors \( (d_{i^*, 1}, d_{i^*, 2}, w_{i^*}) \in \mathbb{Z}^m \times \mathbb{Z}^m \times \mathbb{Z}^m \) such that

\[
[A \mid A_0 \mid A_1 \mid \ldots \mid A_\ell \mid - D] \cdot \begin{bmatrix} d_{i^*, 1} \\ d_{i^*, 2} \\ \text{id}^1[1]d_{i^*, 2} \\ \vdots \\ \text{id}^1[\ell]d_{i^*, 2} \\ w_{i^*} \end{bmatrix} = u \mod q, \tag{37}
\]

by subtracting \( 37 \) from \( 36 \), we find that

\[
\mathbf{h} = \mathbf{S} \cdot (d_1^* - d_{i^*, 1}) + (S_0 + \sum_{j=1}^\ell \text{id}^1[j]S_j) \cdot (d_2^* - d_{i^*, 2}) + (\mathbf{w}^* - w_{i^*}) \tag{38}
\]

is a small-norm vector \( \mathbf{h} \in \mathbb{Z}^m \) satisfying \( \hat{A}_1 \cdot \mathbf{h} = 0 \mod q \). We claim that \( \mathbf{h} \neq 0 \) with high probability. Indeed, we know that \( \mathbf{w}^* \neq w_{i^*} \) if \( \neg \text{fail} \) occurs. This implies that the last term of \( 38 \) is non-zero, which rules out that \( (d_1^*, d_2^*) = (d_{i^*, 1}, d_{i^*, 2}) \).

Since the columns of \( \mathbf{S} \) and \( \{S_j\}_{j=0}^\ell \) have a lot of entropy conditionally on \( \mathcal{Y} \), this
implies that we can only have $h = 0^m$ with negligible probability. Furthermore, the norm of $h$ can be bounded by $\|h\|_2 \leq 4\sigma^2 m^{3/2}(\ell + 2) + 2m^{1/2}$, so that $(h^T | 0^m)^T$ solves the original SIS instance.

- If $coin = 2$, $B$ is done as well since the collision \((30)\) directly provides a vector $h = \bin(v^*) - \bin(v^*_i) + Q \cdot (s^* - s^*_i) \in \mathbb{Z}^{2m}$ of $\Lambda_q^+(D_0)$ (which is also in the lattice $\Lambda_q^+(\tilde{A})$ by construction) and has norm $\|h\|_2 \leq 2(\sigma^2(2m)^{3/2} + (2m)^{1/2})$. Moreover, $h \in \mathbb{Z}^{2m}$ is non-zero with overwhelming probability given that $\bin(v^*) \neq \bin(v^*_i)$ and the large amount of entropy retained by the columns $Q \in \mathbb{Z}^{2m \times 2m}$ given $D_1 = D_0 \cdot Q$. \hfill $\square$

\section*{C.2 Proof of Theorem 5}

\textit{Proof.} Let us assume that a PPT adversary $A$ can create a forgery $(M^*, \Sigma^*)$ that opens to some honest user $i \in U^h$ who did not sign $M^*$. In the random oracle model, we give a reduction $B$ that uses $A$ to solve an instance of the \text{SIS}_{4n,4m,q,\beta} problem: $B$ takes as input $\tilde{A} \in \mathbb{Z}_q^{4n \times 4m}$ and finds a non-zero short vector $w \in \Lambda_q^+(\tilde{A})$.

Algorithm $B$ generates the group public key $\mathcal{Y}$ by faithfully running the real setup algorithm with the sole difference that, at step 2 of Setup, $B$ defines $F = \tilde{A} \in \mathbb{Z}_q^{4n \times 4m}$. However, the distribution of $\mathcal{Y}$ is as in the real scheme. As a result of having generated $\mathcal{Y}$ itself, $B$ knows $\mathcal{S}_{GM} = T_A$ and $\mathcal{S}_{OA} = T_B$. The adversary $B$ is run on input of the group public key

$$\mathcal{Y} := (A, \{A_j\}_{j=0}^\ell, B, D, D_0, D_1, F = \tilde{A}, u, \Pi^{OTS}, H, H_0).$$

If $A$ chooses to corrupt the group manager or the opening authority during the game, $B$ is able to reveal $\mathcal{S}_{GM} = T_A$ and $\mathcal{S}_{OA} = T_B$. Then, $B$ starts interacting with $A$ as follows.

- $Q_{\text{keyGM}}$-queries: If $A$ decides to corrupt the group manager, $B$ hands the secret key $\mathcal{S}_{GM} = T_A$ to $A$.
- $Q_{\text{b-join}}$-queries: At any time $A$ can act as a corrupted group manager and introduce a new honest user $i$ in the group by invoking the $Q_{\text{b-join}}$ oracle. At each $Q_{\text{b-join}}$-query, $B$ faithfully runs $J_{\text{user}}$ on behalf of the honest user in an execution of Join protocol.
- $Q_{\text{pub}}$-queries: These can be answered as in the real game, by having the simulator return $\mathcal{Y}$.
- $Q_{\text{sig}}$-queries: When the adversary $A$ requests user $i \in U^b$ to sign a message $M$, $B$ first generates a one-time key pair $(VK, SK) \leftarrow \mathcal{G}(n)$ to compute $G_0 = H_0(VK) \in \mathbb{Z}_q^{n \times 2m}$. Next, $B$ recalls the vector $z_i \in \mathbb{Z}_q^{m}$ that was chosen to define the syndrome $v_i = F \cdot z_i$ at step 1 of the Join protocol as well as the identifier $\text{id}_i \in \{0,1\}^t$ and the short vectors $(d_{i,1}, d_{i,2}, s_i)$ that were supplied by $A$ in an earlier $Q_{\text{b-join}}$-query. It faithfully computes a signature by IBE-encrypting $\bin(v_i) \in \{0,1\}^{2m}$ and using $(d_{i,1}, d_{i,2}, s_i, z_i, s_i, \text{id}_i)$ to compute a
Finally, $B$ computes a one-time signature $sig = S(SK, (c_{v_i}, \pi_K))$ and returns the signature $\Sigma = (VK, c_{v_i}, \pi_K, sig)$ to $A$.

When $A$ halts, it outputs a signature $\Sigma^* = (VK^*, c_{v_i}^*, \pi_K^*, sig^*)$ for some message $M^*$, which opens to $i^* \in U^b$ although user $i^*$ did not sign the message $M^*$ at any time. Since $(M^*, \Sigma^*)$ supposedly frames user $i^*$, the opening of $\Sigma^*$ must reveal the $m$-bit string $\text{bin}(v_{i^*}) \in \{0,1\}^m$. We note that the reduction $B$ has recollection of a short vector $z_{i^*} \in \mathbb{Z}^{4m}$ (of norm $\|z_{i^*}\| < 2\sqrt{m}$) such that $v_{i^*} = F \cdot z_{i^*} \mod q$ which it chose when running $J_{\text{user}}$ on behalf of user $i^*$ when this user was introduced in the group. Hence, $B$ would be able to solve its given SIS instance if it had another short vector $z' \in \mathbb{Z}^{4m}$ satisfying $v_{i^*} = F \cdot z' \mod q$.

To compute such a vector, $B$ proceeds by replaying the adversary $A$ sufficiently many times and applying the Improved Forking Lemma of Brickell et al. [24].

If we parse $\pi_K^*$ as $(\{\text{Comm}_{K,j}^*\}_{j=1}^t, \text{Chall}_{K^*}, \{\text{Resp}_{K,j}^*\}_{j=1}^t)$, with high probability, $A$ must have queried $H$ on the input $(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$. Otherwise, we would only have $\text{Chall}_{K^*} = H(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$ with negligible probability $3^{-t}$. It comes that, with probability at least $\varepsilon := \varepsilon - 3^{-t}$, the tuple $(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$ was the input of the $\kappa^*$-th random oracle query for some index $\kappa^* \leq Q_H$.

At this point, the reduction $B$ runs the adversary $A$ up to $32 \cdot Q_H / (\varepsilon - 3^{-t})$ times with the same random tape and input as in the first run. All queries are answered as previously with one difference in the way to handle $H$-queries. Namely, the first $\kappa^* - 1$ $H$-queries – which are the same as in the first execution since $A$ is run with the same random tape – obtain the same answers $\text{Chall}_{1,\ldots,\kappa^* - 1}$ as in the original run. This implies that the $\kappa^*$-th query will also involve exactly the same tuple $(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$ as in the original run. From the $\kappa^*$-th query forward, however, the adversary $A$ obtains fresh random oracle outputs $\text{Chall}_{\kappa^* + 1, \ldots, \kappa^* + Q_H}$ at each new execution. The Improved Forking Lemma et al. [24] ensures that, with probability greater than $1/2$, $B$ obtains a 3-fork involving the tuple $(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$ of the initial run and with pairwise distinct answers $\text{Chall}_{(1), \kappa^*}, \text{Chall}_{(2), \kappa^*}, \text{Chall}_{(3), \kappa^*} \in \{1, 2, 3\}^t$. Since the forgeries of the 3-fork all correspond to the tuple $(M^*, VK^*, c_{v_i}^*, \{\text{Comm}_{K,j}^*\}_{j=1}^t)$, they open to the same $m$-bit string $\text{bin}(v_{i^*}) \in \{0,1\}^m$ and which is uniquely determined by $c_{v_i}^*$. In turn, this implies that the three forgeries all reveal the same $\text{bin}(v_{i^*})$ at the second step of $\text{Open}$. With probability $1 - (7/9)^t$ it can be shown that there exists $j \in \{1, \ldots, t\}$ such that the $j$-th bits of $\text{Chall}_{(1), \kappa^*}, \text{Chall}_{(2), \kappa^*}, \text{Chall}_{(3), \kappa^*}$ are $(\text{Chall}_{(1), \kappa^*}, \text{Chall}_{(2), \kappa^*}, \text{Chall}_{(3), \kappa^*}) = (1, 2, 3)$. From the corresponding responses $(\text{Resp}_{K,j}^{(1)}, \text{Resp}_{K,j}^{(2)}, \text{Resp}_{K,j}^{(3)})$, $B$ is able to extract a short vector $z' \in \mathbb{Z}^{4m}$ such that $v_{i^*} = F \cdot z' \mod q$.

Due to the statistical witness indistinguishability of the Stern-like proof of knowledge which is used to generate signature, with overwhelming probability, we have $z' \neq z_{i^*}$. Indeed, from the adversary’s view, the distribution of $z_{i^*}$ is $D_{\lambda_{i^*}^v}^{\text{Time}(F), \sigma}$, which means that it has at least $n$ bits of min-entropy. Hence, the difference $h = z' - z_{i^*} \in \mathbb{Z}^{4m}$ is a suitably short non-zero vector of $\Lambda_4^v(\mathbb{A})$. \hfill $\Box$
C.3 Proof of Theorem 6

Proof. We will proceed as in [13]: we will prove the anonymity through an hybrid argument using a sequence of indistinguishable games. The first game Game 0 is the real experiment and the last one will be such that $\text{Adv}_A(\text{Game } 6) = 0$

**Game 0:** This is the real CCA-anonymity game. The challenger runs algorithm $\text{Setup}(1^\lambda, 1^{N_\sigma})$ to obtain $(\mathcal{Y}, S_{\sigma A}, S_{GM})$ and then gives $\mathcal{Y}$ and $S_{GM}$ to the attacker $A$. Using the secret key $S_{\sigma A}$, the challenger is able to answer all the signatures opening queries. In the challenge phase, $A$ sends a message $M^*$ together with two pairs $(\text{sec}^*_d, \text{cert}^*_d), (\text{sec}^*_d, \text{cert}^*_d)$, where $\text{sec}^*_d = z^*_d \in \mathbb{Z}^m$ and $\text{cert}^*_d = (id^*_d, d^*_d, s^*_d) \in \{0, 1\}^\ell \times \mathbb{Z}^{2m} \times \mathbb{Z}^{2m}$ for each $d \in \{0, 1\}$. The challenger sends back a challenge signature $\Sigma^* = (\text{VK}^*, c^*_v, \pi^*_K, \text{sig}^*) \leftarrow \text{Sign}(\mathcal{Y}, \text{cert}^*_d, \text{sec}^*_d, M^*)$ for a chosen bit $b$. Then the adversary returns a bit $b'$. The experiment return 1 if $b = b'$ or 0 otherwise.

**Game 1:** In this experiment, we slightly modify Game 0: at the outset of the game, the challenger generates the one-time signature key pair $(\text{VK}^*, \text{SK}^*)$. During the game, if $A$ requests the opening of a valid signature $\Sigma = (\text{VK}, c_v, \pi_K, \text{sig})$ where $\text{VK} = \text{VK}^*$, the challenger returns a random bit and abort. However, this event $F_1$ would contradict the strong unforgeability of the one-time signature $\Pi^{OTS}$. Indeed, before the challenge phase $\text{VK}^*$ is independent of $A$’s view and the probability that $\text{VK}^*$ shows up in $A$’s queries is negligible. Moreover, after seeing the challenge signature $\Sigma^*$, if $A$ comes up with a valid signature $\Sigma = (\text{VK}, c_v, \pi_K, \text{sig})$ such that $\text{VK} = \text{VK}^*$, then $\text{sig}$ is a forged one-time signature, which defeats the strong unforgeability of $\Pi^{OTS}$. Therefore the probability $\Pr[F_1]$ that the challenger aborts in this experiment is negligible. From here on, we thus assume that $A$’s opening queries for valid signatures do not include $\text{VK}^*$.

**Game 2:** In this game, we program the random oracle $H_0$ in the following way: at the beginning of the game, we choose a uniformly random matrix $G^*_0 \in \mathbb{Z}_q^{\times 2m}$ and set $H_0(\text{VK}^*) = G^*_0$. From the attacker’s point of view, the distribution of $G^*_0$ is statistically close to the one in the real attack game, as in [13]. As for other queries, for each fresh $H_0$-queries on $\text{VK}$, the challenger samples small-norm matrices $E_{0,\text{VK}} \leftarrow D_{\mathbb{Z}_q^{2m\times 2m}}^2$ and programs the oracle such that $H_0(\text{VK}) = B \cdot E_{0,\text{VK}} \mod q$. The chosen matrices $E_{0,\text{VK}}$ are retained for later note. Note that the values of $H_0(\text{VK})$ are statistically close to the uniform. For any query involving a previously queried $\text{VK}$, the challenger consistently returns the previously stored images. The view of the attacker remains the same as in Game 1, as in the security proof of the GPV IBE [13].

**Game 3:** Here, we will change the behaviour of the opening algorithm. Namely, at each fresh oracle query, we still store the matrices $E_{0,\text{VK}} \in \mathbb{Z}_q^{m \times 2m}$ and, at the beginning of the game, the challenger samples an uniformly random $B^* \in \mathbb{Z}_q^{n \times m}$. When the adversary queries the opening of a signature $\Sigma = (\text{VK}, c_v, \pi_K, \text{sig})$, $B$ recalls the small-norm matrices $E_{0,\text{VK}}$ which were defined when $A$ first queried $H_0(\text{VK})$. These matrices are used as “decryption matrices” to open $\Sigma$ for the corresponding $G_0 = H_0(\text{VK}) \in \mathbb{Z}_q^{n \times 2m}$. Similarly to the security proof [13], the
distribution of $G_0$ is statistically close to the uniform, implying that Game 2 and Game 3 are statistically indistinguishable.

**Game 4:** Instead of faithfully generating the NIZKPoK $\pi_K$, the challenger simulates the proof without using the witness (note that this is possible since the HVZK property of the underlying proof system is preserved under parallel repetitions). This is done by running the simulator for the underlying interactive protocol for each $j \in 1, \ldots, t$, and then programming the random oracle $H$ accordingly. The challenge signature $\Sigma^* = (\text{VK}^*, c_v^*, \pi^*_K, \text{sig}^*)$ is statistically close to the challenge signature of the previous game, because the proof system is statistically zero-knowledge. Consequently, Game 3 and Game 4 are indistinguishable.

**Game 5:** In this game, we change the generation of the ciphertext $c_v^*$ in the challenge phase. Instead of using the real encryption algorithm of the GPV IBE to compute $c_v^*$, we return truly random ciphertexts. In other words, we let

$$c_v^* = \begin{pmatrix} z_1 \\ z_2 + \bin(v^*_b) \lfloor q/2 \rfloor \end{pmatrix},$$

where $v^*_b = F \cdot z^*_b$, and where $z_1 \leftarrow U(\mathbb{Z}_m^q)$, $z_2 \leftarrow U(\mathbb{Z}_m^{2q})$ are uniformly random. The hardness of the decisional $\text{LWE}_{q,\alpha}$ problem implies that $c_v^*$ in Game 4 and Game 5 are computationally indistinguishable. If $A$ can distinguish between these two games, it can distinguish

$$\begin{pmatrix} B^T \\ G^*_0 \end{pmatrix} e_0 + \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \text{ from } \begin{pmatrix} z_1 \\ z_2 \end{pmatrix},$$

which would break the decisional $\text{LWE}_{q,\alpha}$ assumption. Therefore, Game 4 and Game 5 are computationally indistinguishable.

**Game $G^{(6)}$:** Finally we make a conceptual modification on the previous game. Namely we sample uniformly random $z^*_1 \leftarrow U(\mathbb{Z}_m^q)$, $z^*_2 \leftarrow U(\mathbb{Z}_m^{2q})$ and assign

$$c_v^* = \begin{pmatrix} z^*_1 \\ z^*_2 \end{pmatrix}.$$ 

Clearly, the distribution of $c_v^*$ has not changed since Game 5. Since Game 6 does no longer depend on the challenger’s bit $b \in \{0, 1\}$, the result follows. $\square$

### D Proof of Lemma 8

We first restate Lemma 8.

**Lemma 11.** The protocol in Figure 1 is a $\text{sZKAoK}$ for the relation $R_{\text{abstract}}$ with perfect completeness, soundness error $2/3$, and communication cost $\tilde{O}(L \log q)$. In particular:

- There exists an efficient simulator that, on input $(\mathbf{M}, \mathbf{c})$, outputs an accepted transcript which is statistically close to that produced by the real prover.
There exists an efficient knowledge extractor that, on input a commitment 
CMT and 3 valid responses (RSP₁, RSP₂, RSP₃) to all 3 possible values of 
the challenge Ch, outputs x′ ∈ VALID such that M · x′ = c mod q.

Proof. Note that, by construction, the protocol is perfectly complete: If an honest 
prover follows the protocol, then he always gets accepted by the verifier. It is 
also easy to see that the communication cost is bounded by \(O(L \log q)\).

We now will prove that the protocol is a statistical zero-knowledge argument 
of knowledge for the relation R_{abstract}.

Zero-Knowledge Property. We construct a PPT simulator SIM interacting 
with a (possibly dishonest) verifier \(\hat{V}\), such that, given only the public input, SIM 
outputs with probability negligibly close to \(2/3\) a simulated transcript that is 
statistically close to the one produced by the honest prover in the real interaction.

The simulator first chooses a random \(\overline{Ch} \in \{1, 2, 3\}\). This is a prediction of 
the challenge value that \(\hat{V}\) will not choose.

Case \(\overline{Ch} = 1\): Using basic linear algebra over \(\mathbb{Z}_q\), SIM computes a vector \(x' \in \mathbb{Z}_q^n\) such that \(M · x' = c \text{ mod } q\). Next, it samples \(r \leftarrow U(\mathbb{Z}_q^n), \pi \leftarrow U(S)\), 
and randomness \(ρ₁, ρ₂, ρ₃\) for COM. Then it sends the commitment \(CMT = (C₁', C₂', C₃')\) to \(\hat{V}\), where

\[
C₁' = \text{COM}(π, M · r; ρ₁), \quad C₂' = \text{COM}(T_π(r); ρ₂), \quad C₃' = \text{COM}(T_π(x' + r); ρ₃).
\]

Receiving a challenge \(Ch\) from \(\hat{V}\), the simulator responds as follows:
- If \(Ch = 1\): Output \(⊥\) and abort.
- If \(Ch = 2\): Send \(RSP = (π, x' + r, ρ₁, ρ₃)\).
- If \(Ch = 3\): Send \(RSP = (π, r, ρ₁, ρ₂)\).

Case \(\overline{Ch} = 2\): SIM samples \(x' \leftarrow U(\text{VALID}), \quad r \leftarrow U(\mathbb{Z}_q^n), \quad \pi \leftarrow U(S)\), 
and randomness \(ρ₁, ρ₂, ρ₃\) for COM. Then it sends the commitment \(CMT = (C₁', C₂', C₃')\) to \(\hat{V}\), where

\[
C₁' = \text{COM}(π, M · r; ρ₁), \quad C₂' = \text{COM}(T_π(r); ρ₂), \quad C₃' = \text{COM}(T_π(x' + r); ρ₃).
\]

Receiving a challenge \(Ch\) from \(\hat{V}\), the simulator responds as follows:
- If \(Ch = 1\): Send \(RSP = (T_π(x'), T_π(r), ρ₂, ρ₃)\).
- If \(Ch = 2\): Output \(⊥\) and abort.
- If \(Ch = 3\): Send \(RSP = (π, r, ρ₁, ρ₂)\).

Case \(\overline{Ch} = 3\): SIM samples \(x' \leftarrow U(\text{VALID}), \quad r \leftarrow U(\mathbb{Z}_q^n), \quad \pi \leftarrow U(S)\), 
and randomness \(ρ₁, ρ₂, ρ₃\) for COM. Then it sends the commitment \(CMT = (C₁', C₂', C₃')\) to \(\hat{V}\), where \(C₂' = \text{COM}(T_π(r); ρ₂), \quad C₃' = \text{COM}(T_π(x' + r); ρ₃)\) as in the previous two cases, while

\[
C₁' = \text{COM}(π, M · (x' + r) - c; ρ₁).
\]

Receiving a challenge \(Ch\) from \(\hat{V}\), it responds as follows:
– If $Ch = 1$: Send RSP computed as in the case $(\overline{Ch} = 2, Ch = 1)$.
– If $Ch = 2$: Send RSP computed as in the case $(\overline{Ch} = 1, Ch = 2)$.
– If $Ch = 3$: Output $\perp$ and abort.

We observe that, in every case we have considered above, since $\text{COM}$ is statistically hiding, the distribution of the commitment $\text{CMT}$ and the distribution of the challenge $Ch$ from $\hat{V}$ are statistically close to those in the real interaction. Hence, the probability that the simulator outputs $\perp$ is negligibly close to $1/3$. Moreover, one can check that whenever the simulator does not halt, it will provide an accepted transcript, the distribution of which is statistically close to that of the prover in the real interaction. In other words, we have constructed a simulator that can successfully impersonate the honest prover with probability negligibly close to $2/3$.

**Argument of Knowledge.** Suppose that $RSP_1 = (t_x, t_r, \rho_2, \rho_3)$, $RSP_2 = (\pi_2, y, \rho_1, \rho_3)$, $RSP_3 = (\pi_3, r_3, \rho_1, \rho_2)$ are 3 valid responses to the same commitment $\text{CMT} = (C_1, C_2, C_3)$, with respect to all 3 possible values of the challenge. The validity of these responses implies that:

\[
\begin{cases}
  t_x \in \text{VALID}; \\
  C_1 = \text{COM}(\pi_2, M \cdot y - c; \rho_1) = \text{COM}(\pi_3, M \cdot r_3; \rho_1); \\
  C_2 = \text{COM}(t_r; \rho_2) = \text{COM}(T_{\pi_3}(r_3); \rho_2); \\
  C_3 = \text{COM}(t_x + t_r; \rho_3) = \text{COM}(T_{\pi_2}(y); \rho_3). 
\end{cases}
\]

Since $\text{COM}$ is computationally binding, we can deduce that:

$t_x \in \text{VALID}; \pi_2 = \pi_3; t_r = T_{\pi_3}(r_3); t_x + t_r = T_{\pi_2}(y); M \cdot y - c = M \cdot r_3 \mod q.$

Let $x' = y - r_3$, then we have $T_{\pi_2}(x') = t_x \in \text{VALID}$ which implies that $x' \in \text{VALID}$. Furthermore, we have $M \cdot x' = M \cdot (y - r_3) = c \mod q.$

This concludes the proof. $\square$
