HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Iterators: where folds fail

This paper is about the formal verification of a floating-point case study where the common iterators \texttt{fold_left} and \texttt{fold_right} have not the wanted behaviors. We then had to define other iterators, which are very similar in most cases, but that do behave well in our case study.

Our case study: floating-point expansions

This is about floating-point arithmetic, defined by the IEEE-754 standard \[7, 4\]. It has been formalized in the Coq proof assistant by the Flocq library \[2\].

Our case study is a way to increase the precision of a computation, in order to get more accuracy on critical systems. To retain efficiency, we rely on the floating-point unit (FPU) of the processor. The idea of these floating-point expansions is to consider \(x\) as \(x = \sum x_i\) with the \(x_i\) being floating-point numbers, see Figure 1. Using exact addition and multiplication \[3, 6\], we can build correct operations on these expansions such as addition, multiplication, division, and so on \[3, 5, 9, 1\].

We are in the progress of proving operations on expansions. It is important as there may be intermediate zeroes in these expansions that may endanger the algorithms. Moreover, the condition of use of these algorithm: allowed overlap, underflow, overflow, and so on are hardly known, and not formally verified.

Iterators

Here is the Coq definition of fold_left:

```coq
Fixpoint fold_right (l: list B) : A :=
  match l with
    | nil => a0
    | cons b t => f b (fold_right t)
  end.
```

In particular, it relies on the definition of \( a_0 : A \) that stands for the zero of \( A \). For real numbers, we can consider \( \text{fold_right} \ Rplus \ R0 \ (1::2::3::\text{nil}) \) that will be simplified in \( 1 + (2 + (3 + 0)) \). This is perfect as \( \text{Rplus} \) is the mathematical + on \( \mathbb{R} \) with \( \text{R0} = 0 \) is the identity element. If you consider \( f \) as the floating-point addition, it is fine as \( 0 \) is also an identity element for this function.

Now consider the function \( \text{errf} (x, y) = \circ (x + y) - (x + y) \), with \( \circ \) being a rounding to nearest. Then \( f \) computes the error of the floating-point addition, which is also a floating-point number when \( x \) and \( y \) are floating-point numbers, and that may be computed using only floating-point operations \([3, 6]\). Then \( \text{fold_right} \ \text{errf} \ R0 \ (a::b::c::\text{nil}) \) is \( \text{errf} a \ (\text{errf} b \ (\text{errf} c \ 0)) \). As \( \text{errf}(x, 0) = 0 \), this value is 0 whatever \( a, b \) and \( c \). And this is not what we want as we wished to have \( \text{errf} a \ (\text{errf} b \ c) \). This is not a toy example as such an iteration of \( \text{errf} \) on a sequence is the first part of a renormalization algorithm \([4]\).

Solution

Of course, this problem with \( \text{fold_right} \) also applies to \( \text{fold_left} \). We have therefore defined two other iterators:

```coq
Definition my_iter_l f l :=
  match l with
    | nil => 0
    | x :: l => fold_left f l x
  end.
```

```coq
Definition my_iter_r f l :=
  match l with
    | nil => 0
    | _ => fold_right f (last l 0) (removelast l)
  end.
```

They have the expected behavior on the previous example. The correctness of \( \text{my_iter_r} \) is given by the following theorem:

```coq
Lemma my_iter_r_fold_right : forall (f:R -> R -> R) b l,
  (forall x, f x b = x) -> (l <> nil \ / b = 0) ->
  my_iter_r f l = fold_right f b l.
```
If there exists an identity element $b$, then the two iterators have the same result, providing either $b = 0$ or the list is not empty. A similar result for my_iter_l is useless as it simplifies immediately on fold_left as soon as the list is non empty. Several useful lemmas have also been proved, such as

\[
\text{my_iter_l f l} = \text{my_iter_r} (\text{fun } x y \Rightarrow f y x) \ (\text{rev} \ l).
\]

As a conclusion, we have defined other iterators that comply with our needs. In particular, they do not expect an identity element on the function, but are more difficult to handle in the proofs. They could have been made more generic, in the returned value when the list is empty (here 0), and in the input type (here $\mathbb{R}$). It is nevertheless surprising that this problem has not arisen before on other applications.
