L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

HESSIAN TRANSFER FOR MULTILEVEL AND ADAPTIVE SHAPE OPTIMIZATION

B. ABOU EL MAJD*, O. OUCHETTO †, J-A. DÉSIDÉRI‡, AND A. HABBAL§

Abstract. We have developed a multilevel and adaption parametric strategies solved by optimization algorithms which require only the availability of objective function values but no derivative information. The key success of these hierarchical strategies refer to the quality of the downward and upward transfers of information. In this paper, we extend our approach when using a derivative-based optimization algorithms. The aim is to better re-initialize the Hessian and the gradient during the optimization process based on our construction of the downward and upward operators. The efficiency of this proposed approach is demonstrated by numerical experiments on an inverse shape model.

Key words. Shape parametric optimization, Hessian and gradient transfer, Multilevel, Adaption, BFGS method.

AMS subject classifications. 93B52, 90C53, 65K10

1. Introduction. We focus on improving the computational efficiency on optimum shape algorithms for application in which the cost functional relies on the prior solution of a complex set of partial-differential equations (PDEs), such as those governing compressible aerodynamics (e.g. the Euler equations), or related coupled disciplines such as structural mechanics (e.g. elasticity), or electromagnetics (e.g. the Maxwell equations). Hence, each evaluation functional is computationally costly. In several papers [1][2][3][4] [5][6], we introduced a conceptual parallel from grid to geometrical parametrization by constructing a full and adaptive multi-level optimum-shape algorithm (FAMOSA), analogous to the classical full multigrid method (FMG) known to have optimum linear complexity with respect to the number of degrees of freedom). We demonstrated the efficiency of this construction for problems of drag reduction for transonic flight, external noise reduction for supersonic flight, and aerodynamic and structural optimization of a business-jet wingshape. Figure 1.1 illustrates an unstructured mesh, composed of 31124 nodes and 173 445 elements, generated around the wing, including a refined area in the vicinity of the shock. Figure 1.2 shows a comparison of the convergence for the three strategies; FMOSA is the most efficient, yielding a shape of better fitness using a smaller computational effort. Using such setting, the wing geometry of an aircraft in transonic flow has been optimized by the minimization of a functional of the form:

$$\mathcal{J}_{OPT} = \frac{C_D}{C_{D0}} + 10^4 \max(0, 0.999 - \frac{C_L}{C_{L0}}). \quad (1.1)$$

C_{D0} and C_{L0} are respectively the drag and lift coefficients corresponding to the initial shape (NACA 0012 section).

Until now, free-optimization techniques, such as the classical simplex search method, the genetic algorithms (GAs) and the particular swarm optimizers (PSOs), has been employed to reach the optimum design. Despite their greater robustness,

FIGURE 1.2. Comparison of the convergence history for the three strategies.

they require a great number of function evaluations and the cost increases with the number of design variable. Another alternative, according to the literature, consists to utilize a derivative-based optimization algorithms that are able to locate the opti-

mum solutions in the expense of only few function evaluations (i.e. with reasonable CPU time). They are often supported by tools that compute the derivatives of the objective function; such as the adjoint techniques [7][8], the Automatic Differentiation (AD) [9][10], the surrogate models (Radial Basis Function(RBF), Artificial Neural Networks (ANN), etc.) [11].

We note that prior to us, we find many applications employing the derivative-based methods with Bézier parametrization. In particular, Marino et al. [12] has used triangular Bézier surface and the optimization is numerically solved by a constrained gradient-based minimization algorithm. In this work, Marino et al. find the gradient-based algorithm more suitable than the evolutionary algorithm.

In this paper, we propose to solve the shape optimisation problem, within multi-level and adaptive strategies, by the BFGS (Broyden Fletcher Goldfarb and Shanno) Quasi Newton method. One of the key properties of BFGS method is its superlinear convergence, which is guarantee under reasonable assumptions [13]. In addition, it works well in practice, even when the initial iterate is far from the solution. Despite these advantages, the initialization of BFGS algorithm by identity may affects the performance of our hierarchical and adaption strategies; this later depend on the quality of transfer operators in order to rigorously construct embedded and nested search space. Thus, our proposed approach consists to well re-initialize the Hessian and the gradient at each change of the search parametric space.

This paper is organized as follow. First, we review the construction of multilevel algorithms, in the context of *parametric shape optimization*. Second, we present the proposed approach for multilevel and adaptive parametric shape optimization. We then present a numerical results on a model problem from calculus of variations. Finally, we conclude and mention some perspectives.

2. Nested Bézier parameterizations for multilevel shape representation. We begin with the simplest situation of a two-dimensional geometry for which we employ a Bézier shape representation:

$$x(t) = \sum_{k=0}^n B_n^k(t) x_k, \quad y(t) = \sum_{k=0}^n B_n^k(t) y_k \quad (2.1)$$

in which the parameter t varies from 0 to 1, n is the degree of the parameterization,

$$B_n^k(t) = C_n^k t^k (1-t)^{n-k} \quad (2.2)$$

is a Bernstein polynomial, $C_n^k = \frac{n!}{k!(n-k)!}$, and

$$P_k = \begin{pmatrix} x_k \\ y_k \end{pmatrix} \quad (k = 0, 1, \dots, n) \quad (2.3)$$

is the generic control point. The coordinates of these control points are split into two vectors

$$X = \{x_k\}, \quad Y = \{y_k\}, \quad k = 0, 1, \dots, n, \quad (2.4)$$

and we refer to the vector X as the *support* of the parameterization, and the vector Y as the *design* vector. Typically, we optimize the design vector for fixed support according to some physical criterion, such as drag reduction in aerodynamics. The somewhat unsymmetrical roles dispensed to the vectors X and Y are chosen to reduce (to n essentially) the dimension of the search space in the optimization phase, which is the most numerically costly and subject to numerical stiffness.

We also use the notation:

$$x(t) = B_n(t)^T X, \quad y(t) = B_n(t)^T Y, \quad (2.5)$$

in which the vector $B_n(t)^T = (B_n^0(t), B_n^1(t), \dots, B_n^n(t))$. In all this article, only supports for which the sequence $\{x_k\}$ is monotone increasing are said to be admissible and considered throughout. Thus, the function $x(t)$ is monotone-increasing and defines a one-to-one mapping of, say, $[0,1]$ onto itself. Recall also the simple formula for the derivative:

$$\frac{dx(t)}{dt} = n \sum_{k=0}^{n-1} B_{n-1}^k(t) (x_{k+1} - x_k) = n B_{n-1}(t)^T \Delta X \quad (2.6)$$

in which Δ denotes the forward-difference operator ($\Delta x_k = x_{k+1} - x_k$) as well as the associated $n \times (n+1)$ matrix.

In the prototypical case of an airfoil, we use such a parametric representation for both the upper and lower surfaces separately. The vertical slope at the leading edge is enforced by the conditions:

$$x_0 = x_1 = 0, \quad y_0 = 0 \quad (2.7)$$

for both surfaces which assures a smooth match; at the trailing edge, we simply have:

$$x_n = 1, \quad y_n = 0 \quad (2.8)$$

for a continuous match.

Our geometrical construction employs the *degree-elevation process*, well-known in the *Computer-Aided Design* literature (see for example [14]). This process permits to cast [2.5] into the following equivalent Bézier parameterization of degree $n+1$:

$$x(t) = \sum_{k=0}^{n+1} B_{n+1}^k(t) x'_k, \quad y(t) = \sum_{k=0}^{n+1} B_{n+1}^k(t) y'_k \quad (2.9)$$

in which the new control points $P'_k = (x'_k, y'_k)$ are obtained from the former by convex combinations:

$$P'_0 = P_0, \quad P'_k = \frac{k}{n+1} P_{k-1} + \left(1 - \frac{k}{n+1}\right) P_k \quad (k = 1, 2, \dots, n), \quad P'_{n+1} = P_n \quad (2.10)$$

obtained by multiplying [2.5] by $(1-t) + t$ and grouping together the monomials in $t^k(1-t)^{n+1-k}$, for each k .

From a theoretical viewpoint, our construction guarantees rigorously nested search spaces, and exact upward transfer operators (from low to high-degree parameterization). Note that, apart from the specified endpoints, the abscissas of the

initial support X are not a subset of the abscissas of any support of a higher degree parameterization. Nevertheless, any Bézier curve given on the initial support can be expressed exactly on any other support of higher degree provided it results from the degree elevation process. The parameterizations are nested, or embedded in one another in this sense precisely.

Based on this concept of Nested Bézier parameterizations, the following theorem introduces the upward and downward transfer operators.

THEOREM 2.1. *Let $X' = \{x'_k\}$ and $X = \{x_k\}$ two nested (by degree elevation process) parametrization supports of degree $n' = n + 1$ and n respectively, t_i ($i = 0, \dots, n'$) and q_i ($i = 0, \dots, n$) two arbitrary partitions of the interval $[0, 1]$. Then, the upward relation (elevation) between X' and X is given by the relation:*

$$X' = (B_{n'})^{-1} B_{n',n} X \quad (2.11)$$

where the generalized Vandermonde matrix $B_{n'}$ and the rectangular matrix $B_{n',n}$ are:

$$B_{n'} = (B_{n'}^j(t_i)) \quad (i = 0, \dots, n'; j = 0, \dots, n') \quad (2.12)$$

$$B_{n',n} = (B_n^j(t_i)) \quad (i = 0, \dots, n'; j = 0, \dots, n) \quad (2.13)$$

and the downward relation (reduction) between X' and X is given by the relation:

$$X = (\bar{B}_n)^{-1} \bar{B}_{n,n'} X' \quad (2.14)$$

where the generalized Vandermonde matrix \bar{B}_n and the rectangular matrix $\bar{B}_{n,n'}$ are:

$$\bar{B}_n = (B_n^j(q_i)) \quad (i = 0, \dots, n; j = 0, \dots, n) \quad (2.15)$$

$$\bar{B}_{n,n'} = (B_{n'}^j(q_i)) \quad (i = 0, \dots, n; j = 0, \dots, n') \quad (2.16)$$

Proof. Let $X = \{x_k\}$ and $X' = \{x'_k\}$ two nested Bézier parametrization supports of degree n' and n respectively. It means that:

$$B_n(t)^T X = B_{n'}(t)^T X' \quad \text{for each } t \in [0, 1] \quad (2.17)$$

Let $\{t_i\}$ ($i = 0, \dots, n'$) arbitrary partition of $[0, 1]$ et $\{e_i\}$ ($i = 0, \dots, n'$) a canonic base of $\mathbb{R}^{n'}$. We first mulpiy the equation (2.17) by e_k ($k = 0, \dots, n'$), then:

$$e_k B_n(t_k)^T X = e_k B_{n'}(t_k)^T X' \quad (2.18)$$

and by adding these equations (2.18) with respect to k , we find the following formula:

$$B_{n'} X' = B_{n',n} X \quad (2.19)$$

where

$$B_{n'} = (B_{n'}^j(t_i)) \quad (i = 0 \dots, n'; j = 0 \dots, n') \quad (2.20)$$

and

$$B_{n',n} = (B_n^j(t_i)) \quad (i = 0 \cdots n', j = 0 \cdots n) \quad (2.21)$$

Since the generalized Vandermonde matrix $B_{n'}$ is invertible, it follows that:

$$X' = (B_{n'})^{-1} B_{n',n} X \quad (2.22)$$

by the same way, we prove the second statement (2.14) by interchanging n and n' . \square In what follows, we note by E_n^N the upward operator from the lower level n to N ($N > n$) and by R_n^N the downward operator. By construction, we have this following property:

$$R_n^N E_n^N = I_n \quad (2.23)$$

To test these two transfer operators, we use the following model problem:

$$\min_Y j_n(Y) = \frac{p^\alpha}{\mathcal{A}} \quad (2.24)$$

in which $x(t)$ is given, smooth and monotone increasing,

$$p = \int_0^1 \sqrt{x'(t)^2 + y'(t)^2} \omega(t) dt, \quad \mathcal{A} = \int_0^1 y(t) x'(t) \omega(t) dt \quad (\omega > 0, \alpha > 1) \quad (2.25)$$

and

$$x(t) = B_n(t)^T X, \quad y(t) = B_n(t)^T Y, \quad (2.26)$$

p and \mathcal{A} are, for specified $\omega(t) > 0$ and $\alpha > 1$, the pseudo-length of the arc, and the pseudo-area below the arc. This model problem has been studied in [15] to which we refer for a full description of the numerical test-case which corresponds to $\alpha \approx 2.03$, for the functional is known to be convex, and a certain $\omega(t)$ for which the minimizing shape is the half-thickness distribution of the RAE2822 airfoil.

The figure 2.1(a) (resp. 2.1(b)) illustrates the upward process using E_6^8 (resp. the downward process R_6^8). The curves corresponding to the both parametrizations are superimposed.

3. Hessian and gradient transfer. In this section, we present our approach within a multilevel algorithms and adaption procedure. The subject is to good initialize the optimization process when the parametric search space is changed (first case) and the control polygon is regularized (second case).

3.1. First case. As explained in the previous section, the transfer operators guarantee the construction of nested control polygon with higher degree ($N > n$). To achieve a good transfer of informations, we need to better update the Hessian and the gradient in order to conserve the efficiency of our multilevel strategies.

For fixed support X^0 , let (X^0, Y^0) the solution of the minimization of the problem (2.24) and γ_0 the corresponding shape. By using the upward operator, we

FIGURE 2.1. Illustration of E_n^N and R_n^N by using two embedded control polygons of degree $n = 6$ and $N = 8$.

construct a new control polygon (X, Y) of degree N corresponding to the same shape γ_0 . It follows that:

$$\begin{cases} E_n^N X^0 = X \\ E_n^N Y^0 = Y \end{cases} \quad (3.1)$$

and

$$j_N(Y = E_n^N Y^0) = j_n(Y^0) \quad (3.2)$$

where j_N is the cost function of the problem (2.24) corresponding to the Bézier parametrization of degree N .

To express the Hessian and the gradient on the coarse level (of degree n), we differentiate two times the equation (3.2) with respect to Y^0 :

$$\frac{dj_n(Y^0)}{dY^0} = \frac{dj_N(Y)}{dY} E_n^N \quad (3.3)$$

$$\frac{d^2 j_n(Y^0)}{d^2 Y^0} = (E_n^N)^T \frac{d^2 j_N(Y)}{d^2 Y} (E_n^N) \quad (3.4)$$

where $\frac{dY}{dY^0} = E_n^N$.

By differentiating the equation (3.1) with respect to Y , we find:

$$E_n^N \frac{dY^0}{dY} = I_N \quad (3.5)$$

it follows that

$$\frac{dj_N(Y)}{dY} = \frac{dj_n(Y^0)}{dY^0} R_N^n \quad (3.6)$$

and

$$\frac{d^2 j_N(Y)}{d^2 Y} = (R_N^n)^T \frac{d^2 j_n(Y^0)}{d^2 Y^0} (R_N^n) \quad (3.7)$$

where $R_N^n = \frac{dY^0}{dY}$. We note that (3.6) and (3.7) can also be obtained using the property (2.23).

PROPOSITION 3.1. *The Hessian matrix given by (3.7) is positive definite.*

Proof. Let

$$B_n = \frac{d^2 j_n(Y^0)}{d^2 Y^0} \quad \text{and} \quad B_N = \frac{d^2 j_N(Y)}{d^2 Y} \quad (3.8)$$

The matrix B_n is the BFGS approximation corresponding to the first optimization phase on the coarse level; thus, it is positive definite.

Let $x \in \mathbb{R}^N$ ($x \neq 0$), then

$$\begin{aligned} x^T B_N x &= x^T (R_n^N) B_n (R_n^N)^T x \\ &= W_n^T B_n W_n \end{aligned} \quad (3.9)$$

where $W_n = (R_n^N)^T x$.

Since $W_n \neq 0$ and B_n is positive definite, then $x^T B_N x > 0$. It follows that B_N is positive definite. \square As consequence, the following expression holds:

$$\left(\frac{d^2 j_N(Y)}{d^2 Y} \right)^{-1} = (E_n^N) \left(\frac{d^2 j_n(Y^0)}{d^2 Y^0} \right)^{-1} (E_n^N)^T \quad (3.10)$$

Finally, we can update the Hessian by the matrices B_N or B_N^{-1} , it depends on the BFGS method used, instead of identity when the parametrization degree is augmented or reduced. The second phase of the optimization in the fine level of degree N is initialized by an exact Hessian matrix.

3.2. Second Case. Suppose that we are placed on the search space of degree n . the parametrisation adaption consists to adapt the support X by alternating two complementary phases:

1. Optimization: optimize the design vector Y for fixed support $X = X^0$ according to some criterion; let Y^0 be the result of this phase.
2. Regularization: given the parametrization (X^0, Y^0) of an approximate optimum shape γ^0 , the new support X^1 is taken to be the better support for which the total variation (TV) in the components of the corresponding vector Y^1 is minimal, such that the correspondent shape γ^1 to (X^1, Y^1) approximates γ^0 in the sense of least squares; substitute X^1 to X^0 .

This adaption procedure has been studied extensively in [1] for two-dimensional parametrization. The extension to three-dimensional optimum design in aerodynamics within the framework of the so-called free-form deformation has been proposed in [16]. It improves noticeably the convergence rate and reduces the numerical stiffness. The main idea consists to redefine the geometrical representation by using regularization techniques. Thus, a new formulation of the Hessian and the gradient is required in order to re-initialize the adaption process by a good regularized solution with equivalent performance.

As the both control polygons (X^0, Y^0) and (X^1, Y^1) correspond to the same performance, it follows that:

$$\mathcal{J}(\gamma^0) = \mathcal{J}(\gamma^1) \quad (3.11)$$

i.e

$$\mathcal{J}([B_n(t)^T X^0, B_n(t)^T Y^0]_0^1) = \mathcal{J}([B_n(t)^T X^1, B_n(t)^T Y^1]_0^1) \quad (3.12)$$

This intrinsic formulation can be transformed into a parametric optimization by:

$$\mathcal{J}_n^X(Y) = \int_0^1 [B_n(t)^T Y - \bar{y}_T(t, X)]^2 B_{n-1}(t)^T \Delta X dt \quad (3.13)$$

where $\bar{y}_T(t, X) = B_n(\tau)^T Y^0$ and $\tau = \tau(t, X)$ is related to the change of support $X^0 \rightarrow X$, and defined by this condition:

$$B_n(\tau)^T X^0 = B_n(t)^T X \quad (3.14)$$

To satisfy the unicity of the solution, we impose that the components of X^0 are monotone increasing.

The derivative of the cost function \mathcal{J}_n^X is given by:

$$\left(\frac{\partial \mathcal{J}_n^X}{\partial Y} \right)^T = \int_0^1 B_n(t) \left[B_n(t)^T Y - \bar{y}_T(t, X) \right] n B_{n-1}(t)^T \Delta X dt = A(X) Y - b(X) \quad (3.15)$$

where

$$A(X) = \int_0^1 B_n(t) B_n(t)^T n B_{n-1}(t)^T \Delta X dt \quad (3.16)$$

and

$$b(X) = \int_0^1 B_n(t) \bar{y}_T(t, X) n B_{n-1}(t)^T \Delta X dt \quad (3.17)$$

The matrix $A(X)$ is real-symmetric positive definite and depends linearly upon the vector X , thus

$$A(X) = \mathcal{A} \otimes X \quad (3.18)$$

where $\mathcal{A} = A'(X)$ is a tensor of order 3, independent of X and \otimes stands for the contracted product.

The minimization of \mathcal{J}_n^X with respect to Y is equivalent to $\frac{\partial \mathcal{J}_n^X}{\partial Y} = 0$. It follows that:

$$A(X) Y = b(X) \quad (3.19)$$

In particular, (X^0, Y^0) and (X^1, Y^1) verify this linear system.

For $X = X^0$, the first and second derivative of (3.13) with respect to Y^0 are given by:

$$\frac{d\mathcal{J}_n^{X^0}(Y^0)}{dY^0} = \frac{d\mathcal{J}_n^{X^1}(Y^1)}{dY^1} \frac{dY^1}{dY^0} \quad (3.20)$$

and

$$\frac{d^2 \mathcal{J}_n^{X^0}(Y^0)}{d^2 Y^0} = \left(\frac{dY^1}{dY^0} \right)^T \frac{d^2 \mathcal{J}_n^{X^1}(Y^1)}{d^2 Y^1} \left(\frac{dY^1}{dY^0} \right) + \frac{d\mathcal{J}_n^{X^1}(Y^1)}{dY^1} \frac{d^2 Y^1}{d^2 Y^0} \quad (3.21)$$

By differentiating the linear system (3.19) with respect to Y^0 , we obtain:

$$A(X^1) \frac{dY^1}{dY^0} = \frac{db(X^1)}{dY^0} \quad (3.22)$$

where

$$\frac{db(X^1)}{dY^0} = \int_0^1 B_n(t) B_n(\tau)^T nB_{n-1}(t)^T \Delta X dt \quad (3.23)$$

As $A(X^1)$ and $\frac{db(X^1)}{dY^0}$ do not depend on Y^0 , then:

$$A(X^1) \frac{d^2 Y^1}{d^2 Y^0} = 0 \quad (3.24)$$

PROPOSITION 3.2. *If all the components of the support X are monotone increasing, then the matrix $A(X)$ given by the formula (3.16) is positive definite.*

Proof. Let $Y \in \mathcal{R}^n$ ($Y \neq 0$). We have

$$\begin{aligned} Y^T A(X) Y &= \int_0^1 Y^T B_n(t) B_n(t)^T Y nB_{n-1}(t)^T \Delta X dt \\ &= \int_0^1 Z^T Z nB_{n-1}(t)^T \Delta X dt \end{aligned} \quad (3.25)$$

where $Z = B_n(t)^T Y$.

As the components of X are monotone increasing, then $\Delta X > 0$ (Δ est the forward difference operator). So, its enough to prove that $Z^T Z \neq 0$. We proceed by contradiction and assume that $Z^T Z = 0$, so $Z = 0$. As $B_n(t)^T$ form a basis of \mathbb{R}^n , then $Y = 0$, which contradicts the first assumption.

□ Since X^1 satisfy the condition of the theorem (3.2), then the matrix $A(X^1)$ is invertible. Thus:

$$\frac{d^2 Y^1}{d^2 Y^0} = 0 \quad (3.26)$$

As consequence,

$$\frac{d^2 \mathcal{J}_n^{X^1}(Y^1)}{d^2 Y^1} = \left(\frac{dY^1}{dY^0} \right) \frac{d^2 \mathcal{J}_n^{X^0}(Y^0)}{d^2 Y^0} \left(\frac{dY^1}{dY^0} \right)^T \quad (3.27)$$

and

$$\left(\frac{d^2 \mathcal{J}_n^{X^1}(Y^1)}{d^2 Y^1} \right)^{-1} = \left(\frac{dY^1}{dY^0} \right) \left(\frac{d^2 \mathcal{J}_n^{X^0}(Y^0)}{d^2 Y^0} \right)^{-1} \left(\frac{dY^1}{dY^0} \right)^T \quad (3.28)$$

The formulas express the relation between the Hessian matrices corresponding to the initial control polygon (X^0, Y^0) and the regularized one (X^1, Y^1) . It permits to re-initialize the optimization process after each parametrization adaption.

4. Numerical experiments. The proposed approach is tested using the model problem, described in the section 3.1, for the first case and the shape-reconstruction problem, described in the section 3.2, for the second one. The numerical optimum is determined by the Quasi-Newton algorithm [17] based on BFGS (Broyden-Fletcher-Goldfarb-Shanno) updated formula. This algorithm is a line search family method, one of the most powerful methods to solve unconstrained optimization problem. It exposes superlinear convergence; resource-intensivity is estimated as $O(n^2)$ per iteration for n -component argument vector. The search direction is given by $s^k = -\mathbf{H}^k \mathbf{G}^k$,

where \mathbf{G}^k and \mathbf{H}^k are respectively the gradient and the Hessian of the objective function. \mathbf{H}^k a symmetric definite matrix, constructed at each iteration, which approximates the Hessian matrix and/or its inverse. In the literature, there are several formulas for the calculation of \mathbf{H}^{k+1} from \mathbf{H}^k . We use here, the BFGS update formula [13],

$$\mathbf{H}^{k+1} = \mathbf{H}^k - \frac{d^k (y^k)^T \mathbf{H}^k + \mathbf{H}^k y^k (d^k)^T}{(y^k)^T d^k} + \left(\frac{1 + (y^k)^T \mathbf{H}^k y^k}{(y^k)^T d^k} \right) \frac{d^k (d^k)^T}{(d^k)^T y^k} \quad (4.1)$$

where $y^k = \mathbf{G}^{k+1} - \mathbf{G}^k$ and $d^k = x^{k+1} - x^k$.

As a starting point, \mathbf{H}^0 can be set to any symmetric positive definite matrix and very often the identity matrix. This initialization has a bad impact on the efficiency of our multilevel and adaption strategies.

In the following numerical experiments, the gradient is calculated analytically and we focus only on the impact of the Hessian transfer. For the model problem, the derivative of the cost function in the search space of degree n is given by:

$$\frac{dj_n(Y)}{dY} = \frac{p^{\alpha-1} \left(\alpha \mathcal{A} \frac{\partial p}{\partial Y} - p \frac{\partial \mathcal{A}}{\partial Y} \right)}{\mathcal{A}^2}$$

with

$$\frac{\partial p}{\partial Y} = \int_0^1 \frac{n B_{n-1}^T(t) y'(t) \Delta}{\sqrt{x'^2(t) + y'^2(t)}} dt$$

and

$$\frac{\partial \mathcal{A}}{\partial Y} = \int_0^1 B_n^T(t) x'(t) \omega(t) dt$$

We use here the formula of the derivative of $y'(t)$ given by $n B_{n-1}^T \Delta Y$, in which Δ is the $n \times (n+1)$ matrix associated with the forward-difference operator ($\Delta Y = y_{k+1} - y_k$).

For the shape-reconstruction problem, the gradient corresponds to the linear system (3.19):

$$\frac{d\mathcal{J}_n^X(Y)}{dY} = A(X) Y - b(X)$$

To Calculate the gradient on the search space of degree $N > n$ (resp. $N < n$), we apply the upward operator E_n^N (resp. the downward operator R_n^N) to X and Y and we substitute.

Figure 4.1(a) provides the convergence history of the basic algorithm for three optimization strategies: at full convergence, with Hessian transfer after 20 iterations and without Hessian transfer (the Hessian is initialized automatically by identity). And the figure 4.1(b) gives the corresponding optimal shapes. Clearly, all the optimization achieve the convergence and the main point is the fact that the strategy

FIGURE 4.1. Basic algorithm for $N = 12$; Comparison between three strategies: full convergence, with Hessian transfer, without Hessian transfer.

based on Hessian transfer has no effect on the convergence rate; so, this experiment validate the formulas of the Hessian and gradient.

In this experiment, the multilevel optimization is considered here for $n = 4$ and $N = 12$. The figures 4.2(a) and 4.2(b) give respectively the iterative performance and the corresponding optimal shapes for the multilevel algorithm with and without Hessian transfer. Clearly, the algorithm based on Hessian transfer is faster in term of the convergence rate. This experiment confirms the impact on the performance of the multilevel algorithm when the Hessian matrix is initialized by identity.

Lastly, we measure the effect of the hessian transfer on the accuracy of the optimization when using the adaption procedure. The Figure 4.3(a) shows a comparison of the basic algorithm for $n = 8$, with the adaption procedure with and without Hessian transfer. The Figure 4.3(b) gives the corresponding optimal shape. As expected, the Hessian transfer guarantees a best convergence rate of the optimization.

5. Conclusion. The Hessian transfer is essential to preserve and enhance the quality of our multilevel strategies and adaption procedure. This approach permits to better initialize the BFGS Quasi-Newton method. The numerical experiments demonstrate clearly its efficiency in the case of two-dimensional model problem. This study, encourage developing a new multilevel geometrical structure in which, for example in the case of two-level ideal V-cycle [19][20], the problem is solved to complete convergence on the coarse level by robust optimization algorithms (Genetic algorithm (GA), Particle swarm optimization (PSO), simplex method,...) and few iterations are enough (acts as preconditionners) in the fine level to alleviate the numerical stiffness; BFGS Quasi-Newton can be used in this case. This variant is illustrated by the following schematic. Others strategies can be elaborated mimicking the multigrid-type strategies (saw-tooth, V and W cycle, FMG, etc.) [18].

The proposed approach will be generalized for 3D optimum design in aerodynamics, structural mechanics, or coupled disciplines within the framework of the so-called Free-Form deformation (FFD) [21]. Testing a great number of promising algorithmic strategies is also a part of our ongoing work.
