#### Abstract

In this paper we propose an algebraic method in order to reduce dynamically the number of search directions during block Conjugate Gradient iterations. Indeed, by monitoring the rank of the optimal step $\alpha_{k}$ it is possible to detect inexact breakdowns and remove the corresponding search directions. We also propose an algebraic criterion that ensures in theory the equivalence between our method with dynamic reduction of the search directions and the classical block Conjugate Gradient. Numerical experiments show that the method is both stable, the number of iterations with or without reduction is of the same order, and effective, the search space is significantly reduced. We use this approach in the context of enlarged Krylov subspace methods which reduce communication when implemented on large scale machines. The reduction of the number of search directions further reduces the computation cost and the memory usage of those methods.

Key-words: linear solvers, block Krylov methods, Conjugate Gradient, inexact breakdowns

[^0]
## Réduction des coûts de communication et de calcul du Gradient Conjugué dans les sous-espaces de Krylov Élargi

Résumé : Dans ce papier, nous proposons une méthode algébrique pour réduire dynamiquement le nombre de directions de recherche pendant les itérations du Gradient Conjugué par bloc. En effet, en mesurant la perte de rang numérique du pas optimal $\alpha_{k}$, il est possible d'enlever les directions de recherche superflues. Nous proposons aussi un critère algébrique qui assure en théorie l'équivalence entre notre méthode avec réduction dynamique des directions de recherche et le Gradient Conjugué par bloc classique. Les résultats numériques obtenus montrent que la méthode est la fois stable, le nombre d'itérations est du mme ordre avec ou sans la réduction, et efficace, l'espace de recherche est significativement réduit. Nous utilisons cette approche dans le contexte des méthodes de Krylov élargis qui réduisent les communications lorsqu'elles sont utilisées sur des machines parallèle grande échelle. La réduction du nombre de directions de recherche réduit encore plus le cot de calcul et l'occupation mémoire de ces méthodes.

Mots-clés : solveur linéaire, méthodes de Krylov par bloc, Gradient Conjugué, perte de rang numérique

## 1 Introduction

Solving linear systems of the form $A x=b$, with $A \in \mathbb{R}^{n \times n}$, is a problem that arises in many academic and industrial applications. We consider in this paper the case of symetric definite positive matrices, i.e. $z^{\top} A y$ is a scalar product in $\mathbb{R}^{n}$, and Krylov subspace methods for solving these systems, more specifically the Conjugate Gradient method by Hestenes and Stiefel [5]. This method has been extensively studied over the years [20, 2].

Solving those linear systems efficiently on large scale computers remains a difficult problem. One challenge is the increased cost of communication with respect to computation [30], which shows that it is important to design or reformulate existing algorithms such that the number of communication instances is significantly reduced. One approach to do so with Krylov subspaces methods is to use Block Krylov subspaces which are larger spaces that can be constructed at the same communication cost as the original one, while leading to a faster convergence. Thus the overall number of communication instances can be drastically reduced.

Those were introduced for the Conjugate Gradient in 1980 by $O^{\prime}$ Leary with the Block Conjugate Gradient method [3] (Block CG). She was motivated by problems which require to solve a linear system with several right hand sides. She has shown theoritically that this method can converge significantly faster than the classical Conjugate Gradient.

In the early 90 s Nikishin and Yeremin [7] introduced a novel method based on the Block Conjugate Gradient to solve a linear system with one right hand side (BRRHS-CG). They propose to reduce the size of the block during the iterations by monitoring the rank of the residual matrix. That way they aim at obtaining the convergence behaviour of the block method while maintaining an acceptable overcost compared to classical Conjugate Gradient. In the late 90s, Brezinski introduced Multi-parameter Descent Methods [13, 14]. Instead of using one search direction at each iteration he proposed to use several. This variant is a hybrid between a block method and a method for solving systems with one right hand side: even if the descent directions and the steps are blocks, as in the block methods, the remaining quantities are vectors, as in classical methods.

More recently Robbé and Sadkane in [4] improved the idea introduced by Nikishin and Yeremin [7] and applied it to GMRES [26]. With a different point of view Bhaya et al. [6] introduced the Cooperative Conjugate Gradient (CoopCG) where several agents cooperate in order to solve a linear system. This method can be seen as Block CG that uses several random initial guesses [8].

Our starting point is the work of Grigori, Moufawad and Nataf from [8] where they introduce the Enlarged Krylov subspaces. They enrich the Krylov subspaces by splitting the residual obtained from the first iteration. In particular, we focus on the Short Recurrence Enlarged CG (EK-CG) method introduced in [8] because it keeps the short recurrence property of the classical Conjugate Gradient. And in fact, this method can be seen as a Multi-parameter Descent Method [13, 14]. The main difference lies in the approach used to construct the descent directions $P_{k+1}$ at iteration $k+1$. In [14] the authors constructed $P_{k+1}$
from the residual matrix $R_{k}$ and the descent directions $P_{k}$ from iteration $k$,

$$
\begin{equation*}
P_{k+1}=R_{k}-P_{k}\left(P_{k}^{\top} A P_{k}\right)^{-1} P_{k}^{\top} A R_{k} \tag{1}
\end{equation*}
$$

This is very close to the original formulation of Block Conjugate Gradient [3] and Conjugate Gradient [5]. In [8] the authors A-orthonormalize the blocks and construct $P_{k+1}$ from the previous descent directions $P_{k}$ and $P_{k-1}$,

$$
\begin{equation*}
P_{k+1}=A P_{k}-P_{k} P_{k}^{\top} A A P_{k}-P_{k-1} P_{k-1}^{\top} A A P_{k} \tag{2}
\end{equation*}
$$

This is a modification of the original Block Lanczos formula,

$$
\begin{equation*}
P_{k+1}=A P_{k}-P_{k} P_{k}^{\top} A P_{k}-P_{k-1} P_{k-1}^{\top} A P_{k} \tag{3}
\end{equation*}
$$

in order to obtain $P_{k}$ which are A-orthonormal to each others instead of being orthonormal.

In this paper we propose a general method to reduce the size of the search directions block during the iterations of a Block CG-like method. Unlike the method presented by Nikishin and Yeremin in [7], which assumes that $P_{k}$ is constructed as in (1), we suppose that $P_{k}$ is obtained using (2). We also propose an algebraic criterion to decide when to reduce the block size. Both the criterion and the reducing method are general and we apply them to BRRHS-CG, CoopCG, and EK-CG. Numerical results show that this method is both effective (the size of the space in which we find the approximated solution is reduced by a factor of one third) and robust (the number of iterations increases by a factor smaller than $5 \%$ ). Moreover we observe that EK-CG is particularly adapted to this method, it leads to the best results in terms of efectiveness and robustness in most of the numerical tests performed.

The paper is organised as follows. In section 2 we recall the definition and some basic properties of the Block CG method. We recall two variants in order to construct the descent directions, Orthomin which is the one used in the original CG method [5], and Orthodir which is based on the Lanczos formula (3).

In section 3 we formulate three methods to solve a linear system with one right hand side using the framework of Block CG: BRRHS-CG [7], Coop-CG [6] and EK-CG [8].

In section 4 we use the same idea as Robbé and Sadkane [4] and adapt their method to reduce dynamically the number of search directions to block CG, both for Orthodir and Orthomin variants. Indeed, by monitoring the rank of $\alpha_{k}=P_{k}^{\top} R_{k-1}$ we are able to reduce the size of the block during the iterations. This method is very general and can be applied to all Block CG-like methods. This allows us to compare BRRHS-CG, Coop-CG and EK-CG with block size reduction.

In section 5 we study the choice of the tolerance for removing the search directions. A theoritical study gives us an algebraic criterion that ensures the equivalence of the method with the one when no reduction is done. From this study, we derive a practical choice that induces no overcost and verifies the
theoritical criterion. This choice does not depend on the method and therefore can be applied to all the methods presented before.

In section 6 we present numerical experiments. First, we compare the Orthodir and Orthomin variants. Numerical results show that Orthodir is always more stable in terms of number of iterations. Then we compare BRRHS-CG, Coop-CG and EK-CG with the classical Preconditioned Conjugate Gradient for the Orthodir variant. We observe that Ek-CG and BRRHS-CG behave similarly and outperform Coop-CG in terms of number of iterations. Finally we compare those 3 methods with block size reduction. Numerical results show that our method is stable when using Orthodir, the number of iterations is increasing slowly when we reduce the size of the block. But when using Orthomin, some untabilities may appear, the number of iterations increases drastically for some of our test matrices (from a linear elasticity problem).

## 2 The Block CG algorithm and the orthodir variant

In this section we recall the definition of the Block CG algorithm according to $O^{\prime}$ Leary [3], also referred to as Orthomin [2]. Then we define the so-called Orthodir [2] variant of the method which leads to a faster convergence in terms of iteration count (see results in section 6).

In what follows we consider the following notations: $U^{\top}$ is the transpose of a matrix $U, A$ is a symetric $\left(A^{\top}=A\right)$ positive definite $\left(x^{\top} A x>0, \forall x \neq 0\right)$ real matrix of size $n \times n, B$ is a real matrix of size $n \times t, B^{(i)}$ is the $i$-th column of a matrix $B, X_{0}$ is an initial guess for the linear system $A X=B$, i.e. it is a real matrix of size $n \times t$. We denote the initial residual matrix $R_{0}=B-A X_{0}$. We call $t$ the initial block size. Unless otherwise stated, $\|$.$\| denotes the usual$ euclidean norm both for vectors and matrices.

Following Gutknecht at al. [10] Block Krylov subspaces are defined as,

$$
\begin{align*}
\mathcal{K}_{k}^{\square}\left(A, R_{0}\right) & :=\operatorname{span}^{\square}\left\{R_{0}, A R_{0}, \ldots, A^{k-1} R_{0}\right\}  \tag{4}\\
& :=\left\{\sum_{s=0}^{k-1} A^{s} R_{0} \gamma_{s} \text { such that } \forall s \in\{0, \ldots, k-1\}, \gamma_{s} \in \mathbb{R}^{t \times t}\right\} . \tag{5}
\end{align*}
$$

When there is no ambiguity we denote $\mathcal{K}_{k}^{\square}\left(A, R_{0}\right)$ by $\mathcal{K}_{k}^{\square}$. Using this definition Block Krylov suspaces projection methods are defined as,

$$
\begin{align*}
& X_{k} \in \mathcal{K}_{k}^{\square}+X_{0}  \tag{6}\\
& R_{k} \perp \mathcal{L}_{k}^{\square} \tag{7}
\end{align*}
$$

where $\mathcal{L}_{k}^{\square}$ is a subspace which has the same size as $\mathcal{K}_{k}^{\square}$. The first equation (6) is called the subspace condition and the second one (7) is called the PetrovGalerkin condition.

The Block Conjugate Gradient method is defined as the Block Krylov subspaces projection method, where A is symmetric positive definite and $\mathcal{L}_{k}^{\square}=\mathcal{K}_{k}^{\square}$. As a result of this projection process,

$$
\begin{equation*}
\phi\left(X_{k}\right)=\min _{X \in \mathcal{K}_{k}^{\square}} \phi(X), \tag{8}
\end{equation*}
$$

where

$$
\begin{align*}
\phi(X) & =\frac{1}{2} X^{\top} A X-B^{\top} X  \tag{9}\\
\nabla \phi(X) & =A X-B \tag{10}
\end{align*}
$$

As in gradient methods, the new solution at iteration $k$ is defined as $X_{k}=$ $X_{k-1}+P_{k} \alpha_{k}$, where $P_{k}$ represent the descent directions and $\alpha_{k}$ is the step. One important property of the Block Conjugate Gradient is the A-orthonormality (or conjugacy) of the descent directions, that is $P_{i}^{\top} A P_{j}=0$ when $i \neq j$. The classical version of Block CG defined by O'Leary [3] is given in Algorithm 1.

Following [8], in our experiments we A-orthonormalize the block of $P_{k}$ by using Pre-CholQR [11]. This algorithm can be found in the appendix of this paper (Algorithm 6). This method is very similar to the one originaly proposed by Hestenes and Stiefel [5] because it constructs the new descent directions $P_{k+1}$ using $R_{k}$ and $P_{k}$.

However in practice we notice that this variant is less effective when $R_{k}$ becomes rank defficient. We will discuss this in more details in section 6 where we will present the numerical results in Table 3. Following Dubrulle [12] it is possible to improve this algorithm by performing a QR decomposition of the residual matrix $R_{k}$ before constructing $P_{k+1}$ but we do not test this method in this paper.

The block version of the Orthodir method defined in [2] is given in Algorithm 2. Unlike the previous variant in Algorithm 2, $P_{k+1}$ is constructed using $P_{k}$ and $P_{k-1}$. This corresponds to the Block Lanczos algorithm but with the inner product induced by $A$.

```
Algorithm 1 Block CG: orthomin
Require: \(A, B, X_{0}, k_{\max }, \varepsilon_{\text {solver }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)
    \(P_{1}=\) A-orthonormalize \(\left(R_{0}\right)\)
    \(k=1\)
    while \(\left\|R_{k-1}\right\|>\varepsilon_{\text {solver }}\|B\|\) and \(k<k_{\max }\) do
        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(P_{k+1}=R_{k}-P_{k} P_{k}^{\top} A R_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

```
Algorithm 2 Block CG: orthodir
Require: \(A, B, X_{0}, k_{\max }, \varepsilon_{\text {solver }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)
    \(P_{0}=0\)
    \(P_{1}=\) A-orthonormalize \(\left(R_{0}\right)\)
    \(k=1\)
    while \(\left\|R_{k-1}\right\|>\varepsilon_{\text {solver }}\|B\|\) and \(k<k_{\text {max }}\) do
        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(P_{k+1}=A P_{k}-P_{k} P_{k}^{\top} A A P_{k}-P_{k-1} P_{k-1}^{\top} A A P_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

Both Orthomin and Orthodir produce $P_{i}$ that are A-orthonormal and belong to the same space. Hence, they are mathematically equivalent in exact arithmetic. Orthodir is twice as expensive as Orthomin but it has the nice property to produce $P_{k+1}$ which is full rank before A-orthonormalization.

Proposition 1 If $\forall i \geq 0, P_{i}$ is $A$-orthonormal and

$$
\begin{equation*}
P_{k+1}=A P_{k}-P_{k} P_{k}^{\top} A A P_{k}-P_{k-1} P_{k-1}^{\top} A A P_{k} \tag{11}
\end{equation*}
$$

then $P_{k+1}$ is full rank.
Proof 1 The first part of the proof is by induction on $k$.

- If $k=0$, it is true by assumption.
- If $k \in\{1, \ldots, n\}$, let us assume that the proposition is true. We proove by contradiction that it is still true at iteration $k+1$. We supppose that the proposition is true at iteration $k$ and that there exists a vector $v$ of size $t$ such that,

$$
\begin{equation*}
P_{k+1} v=0 \tag{12}
\end{equation*}
$$

Then,

$$
\begin{array}{ccl} 
& \left(A P_{k}-P_{k} P_{k}^{\top} A A P_{k}-P_{k-1} P_{k-1}^{\top} A A P_{k}\right) v & =0, \\
\Longleftrightarrow \quad\left(I-P_{k} P_{k}^{\top} A-P_{k-1} P_{k-1}^{\top} A\right) A P_{k} v & =0, \\
\Longleftrightarrow \quad A P_{k} v & =0 . \tag{15}
\end{array}
$$

Hence, $A P_{k}$ is not full rank but both $A$ and $P_{k}$ are full rank and there is a contradiction.

Proposition 1 ensures that using A-CholQR (Algorithm 5) with Orthodir is always possible. There is no breakdown in this case because $P_{k+1}$ is already full rank before its A-orthonormalization. This is not true with Orthomin because the rank $P_{k+1}$ depends of the one of $R_{k}$ and $R_{k}$ becomes rank deficient at some point. Numerical results shown in Table 3 illustrate this. In order to overcome this difficulty, it is possible to use Pre-CholQR (Algorithm 6) instead of ACholQR, as shown in [11]. Even when using Pre-CholQR, Orthomin performs more iterations than Orthodir on very ill-conditioned matrices (Table 3). In the following section we will define a process to reduce the size of the search directions during the iterations both with Orthomin and Orthodir.

## 3 Using Block CG to solve one linear system of equations

Even if the Block CG method was initially used to solve linear systems with several right hand sides [3], it is possible to use a block method to solve a linear system with only one rigth hand side. This is useful because Block CG can converge significantly faster than CG [3]. In the following we present different ways to use Block CG in order to solve a system with only one right hand side.

Let us recall that $A$ is $n \times n$ and $X_{0}, B$ are $n \times t$. The block size is denoted by $t$. We denote $\mathbb{1}_{t}$ a row of size $1 \times t$ and full of ones. We refer to the method defined in [7] by Nikishin and Yeremin as BRRHS-CG. In this method, $X_{0}$ and $B$ are choosen as $X_{0}=x_{0} \mathbb{1}_{t} B^{(i)} \sim \mathcal{U}(0,1), \forall t \geq i>1$ and $B^{(1)}=b$. In that case, the method is stopped as soon as the first column of $R_{k}$ has a norm smaller than $\varepsilon_{\text {solver }}\|b\|$. The solution is given by the first column of $X$. Coop- $C G$ is a method defined by Bhaya et al. in [6] in which $X_{0}$ is a uniform random matrix and $B=b \mathbb{1}_{t}$. As soon as one column of the residual $R$ has a norm smaller than $\varepsilon_{\text {solver }}\|b\|$, the method is stopped. The solution is given by the corresponding column of $X$.

In [8] Grigori, Moufawad and Nataf use a domain decomposition approach to define enlarged Krylov subspaces and the associated $E K-C G$ method. More
precisely given a splitting decomposition represented by the operator $T$,

$$
T(x)=\left(\begin{array}{ccccc}
* & & & & \\
\vdots & & & & \\
* & & & & \\
& * & & & \\
& \vdots & & & \\
& * & & & \\
& & \ddots & & \\
& & & * & \\
& & & \vdots & \\
& & & * & \\
& & & & * \\
& & & & *
\end{array}\right)
$$

and the initial residual $r_{0}$, the corresponding enlarged Krylov subspace is defined as

$$
\begin{equation*}
\mathcal{K}_{k, t}=\operatorname{span}^{\square}\left\{T\left(r_{0}\right), A T\left(r_{0}\right), \ldots, A^{k-1} T\left(r_{0}\right)\right\} . \tag{16}
\end{equation*}
$$

Using this definition and the formula (2) to construct the search directions, they derive a Short Recurrence Enlarged CG. This method can be embedded in the Block Conjugate Gradient framework by defining $R_{0}=T\left(r_{0}\right)$. The stopping criterion is the euclidean norm of $r_{k}=\sum_{i} R_{k}^{(i)}$ and the solution is $x=\sum_{i} X^{(i)}$.

In our experiments we use a splitted block Jacobi preconditioner,

$$
L L^{\top}=\left(\begin{array}{llll}
A_{11} & & & \\
& A_{22} & & \\
& & \ddots & \\
& & & A_{\mathrm{nj} \mathrm{nj}}
\end{array}\right)
$$

with $t<\mathrm{nj}$, and we solve $L^{-1} A L^{-\top} x=L^{-1} b=\widetilde{b}$. In that case the matrix $\widetilde{A}=L^{-1} A L^{-\top}$ is still symmetric positive definite and we can apply all the presented CG variants we presented on the preconditioned system $\widetilde{A x}=\widetilde{b}$. As it is shown in the figure (1), we consider a number of blocks $n j$ which is different (and higher in general) than the block size of the method.

Figure 1: Pattern of the matrix: in red the block Jacobi and in yellow the subdomains corresponding to the partitioning of $r_{0}$.

It is also possible to apply the preconditioner on the left, we solve $M^{-1} A x=$ $M^{-1} b$ with $M=L L^{\top}$. Although numerical results show that the two approaches are equivalent (Table 7), there are some pratical differences. When preconditioning on the left, another vector is needed and the A-orthonormalization is done with respect to $A$ without preconditioning (see Algorithms 7 and 8). This second point is of importance because when using splitted preconditioner A-orthonormalization is done with respect to the preconditioned matrix which is more stable numerically [11].

## 4 Reducing the block size

In this section, we introduce an approach for reducing the block size in the Orthodir method during the iterations. This is a technique known as deflation in block Krylov methods $[10,7,4]$.

Indeed, as explained in the survey [10] the key idea to reduce the block size is to monitor the rank of $R_{k-1}$. Once $R_{k-1}$ becomes rank deficient, it means that there exists a vector $v$ of dimensions $t \times 1$ such that,

$$
\begin{equation*}
R_{k-1} v=0 \tag{17}
\end{equation*}
$$

and,

$$
\begin{align*}
R_{k} v & =R_{k-1} v-A P_{k} \alpha_{k} v  \tag{18}\\
& =0+A P_{k} P_{k}^{\top} R_{k-1} v  \tag{19}\\
& =0 . \tag{20}
\end{align*}
$$

It follows that $R_{i} v=0$ for $i \geq k-1$. In other words, $X_{k-1} v$ has already converged at iteration $k-1$ because $X_{k-1} v=A^{-1} B v$. For $i \geq k-1$, there exists a linear combination (independant of $i$ ) of columns of $X_{i}$ denoted $X_{i} v$ such that $X_{i} v$ remains constant. As a consequence, it is possible to follow [7] and reduce effectively the sizes of $X, R$ and $P$. But as Langou showed in [15], it can lead to unstabilities. It is easy to see, using exactly the same reasoning, that if $\operatorname{rank}\left(R_{k-2}\right)-\operatorname{rank}\left(R_{k-1}\right)=l$ then a part of the solution of dimension $l$ has converged. As $R_{k-1}$ is an $n \times t$ matrix with $n$ large, it is preferable to avoid computing the rank of $R_{k-1}$ directly. Our approach is based on computing the rank of $\alpha_{k}=P_{k}^{\top} R_{k-1}$. This is similar to the idea developped by Robbé and Sadkane in [4]: it is preferable to work with the residual projected onto the Krylov subspace because it is smaller ( $t \times t$ instead of $n \times t)$ and $\operatorname{rank}\left(\alpha_{k}\right)=\operatorname{rank}\left(R_{k-1}\right)$. Indeed, if $\alpha_{k}$ is rank deficient there exists $v$ such that,

$$
\begin{align*}
\alpha_{k} v=0 & \Longrightarrow P_{k}^{\top} R_{k-1} v=0  \tag{21}\\
& \Longrightarrow P_{k}^{\top} u=0 \text { with } u=R_{k-1} v \tag{22}
\end{align*}
$$

and since $P_{k}$ is always full rank after its A-orthonormalization,

$$
\begin{align*}
P_{k}^{\top} u=0 & \Longrightarrow u=0  \tag{23}\\
& \Longrightarrow R_{k-1} v=0 \tag{24}
\end{align*}
$$

Thus $\operatorname{rank}\left(\alpha_{k}\right)=\operatorname{rank}\left(R_{k-1}\right)$ and $R_{i} v=0$ for $i \geq k-1$. It follows that $\alpha_{i} v=0$ for $i \geq k-1$ which means that some search directions are not taken into account anymore. However, in pratice this case, where $\alpha_{k}$ becomes exactly rank deficient (also denoted exact breakdown or lucky breakdown), is very rare and it is preferable to detect when $\alpha_{k}$ becomes nearly rank deficient (also denoted inexact breakdown) [10, 4, 7].

More precisely, we compute the Singular Value Decomposition of $\alpha_{k}$,

$$
\begin{equation*}
\alpha_{k}=U_{k} \Sigma_{k} V_{k}^{\top} \tag{25}
\end{equation*}
$$

where $U_{k}$ and $V_{k}$ are orthonormal $t \times t$ matrices and $\Sigma=\operatorname{diag}\left(\sigma_{t}, \ldots, \sigma_{1}\right)\left(\sigma_{1} \leq\right.$ $\cdots \leq \sigma_{t}$ are the singular values of $\left.\alpha_{k}\right)$. If $\alpha_{k}$ is nearly rank deficient then this decomposition can be rewritten as

$$
U_{k} \Sigma_{k} V_{k}^{\top}=\left(\begin{array}{ll}
U_{k}^{(1)} & U_{k}^{(2)}
\end{array}\right)\left(\begin{array}{cc}
\Sigma_{k}^{(1)} & 0  \tag{26}\\
0 & \Sigma_{k}^{(2)}
\end{array}\right)\binom{V_{k}^{(1)^{\top}}}{V_{k}^{(2)}}
$$

where $\left\|U_{k}^{(2)} \Sigma_{k}^{(2)} V_{k}^{(2)^{\top}}\right\|<\varepsilon_{\text {def }}$, and $\varepsilon_{\text {def }}$ is a given tolerance. In this case $\alpha_{k} \approx$ $U_{k}^{(1)} \Sigma_{k}^{(1)} V_{k}^{(1)^{\top}}$ and the idea is to replace $\alpha_{k}$ by $U_{k}^{(1)} \Sigma_{k}^{(1)} V_{k}^{(1)^{\top}}$. Hence $P_{k} \alpha_{k} \approx$ $\left(P_{k} U_{k}^{(1)}\right)\left(\Sigma_{k}^{(1)} V_{k}^{(1)^{\top}}\right)$.

Now let us define,

$$
\begin{align*}
P_{k}^{(1)} & =P_{k} U_{k}^{(1)},  \tag{27}\\
P_{k}^{(2)} & =P_{k} U_{k}^{(2)}  \tag{28}\\
\alpha_{k}^{(1)} & =\Sigma_{k}^{(1)} V_{k}^{(1)^{\top}} . \tag{29}
\end{align*}
$$

Theorem 1 The part of the solution corresponding to $X_{k} V_{k}^{(2)}$ has almost converged in the $A$-norm. More precisely, if we denote the error $E_{k}=X^{*}-X_{k}$ (of size $n \times t$ ) where $X^{*}$ is the exact solution, and $v$ a column of $V_{k}^{(2)}$,

$$
\begin{align*}
\left\|E_{k} v-E_{k-1} v\right\|_{A} & \leq \varepsilon_{d e f}  \tag{30}\\
\left\|R_{k} v-R_{k-1} v\right\|_{A^{-1}} & \leq \varepsilon_{d e f} \tag{31}
\end{align*}
$$

Proof 2 Let us assume that $v$ is the $j^{\text {th }}$ column of $V_{k}^{(2)}$. We denote $\sigma_{j}$ the corresponding singular value, it corresponds to the $j^{\text {th }}$ diagonal value in $\Sigma_{k}^{(2)}$. We have,

$$
\begin{align*}
\left\|X_{k} v-X_{k-1} v\right\|_{A} & =\left\|X_{k-1} v+P_{k} U_{k}^{(2)} \sigma_{j} v-X_{k-1} v\right\|_{A}  \tag{32}\\
& =\left\|P_{k}^{(2)} \Sigma_{k}^{(2)} v\right\|_{A}  \tag{33}\\
& =\sqrt{\sigma_{j} v^{\top} P_{k}^{(2)}{ }^{\top} A P_{k}^{(2)} v \sigma_{j}}  \tag{34}\\
& =\sqrt{\sigma_{j}^{2}}  \tag{35}\\
& =\sigma_{j}  \tag{36}\\
& \leq \varepsilon_{d e f .} \tag{37}
\end{align*}
$$

Similarly,

$$
\begin{align*}
\left\|R_{k} v-R_{k-1} v\right\|_{A^{-1}} & =\left\|R_{k-1} v+A P_{k} U_{k}^{(2)} \sigma_{j} v-R_{k-1} v\right\|_{A^{-1}}  \tag{38}\\
& =\left\|A P_{k}^{(2)} \Sigma_{k}^{(2)} v\right\|_{A^{-1}}  \tag{39}\\
& =\sqrt{\sigma_{j} v^{\top} P_{k}^{(2)}{ }^{\top} A A^{-1} A P_{k}^{(2)} v \sigma_{j}}  \tag{40}\\
& =\sqrt{\sigma_{j}^{2}}  \tag{41}\\
& =\sigma_{j}  \tag{42}\\
& \leq \varepsilon_{\text {def. }} \tag{43}
\end{align*}
$$

Since the part of the solution corresponding to $X_{k} V_{k}^{(2)}$ has almost converged (in the A-norm), the search directions $P_{k}^{(2)}$ are not needed anymore. Hence we
define the new search directions as,

$$
\begin{align*}
P_{k+1} U_{k}^{(1)}= & A P_{k}^{(1)}-\left(\begin{array}{ll}
P_{k}^{(1)} & P_{k}^{(2)}
\end{array}\right)\binom{\left.P_{k}^{(1)}\right)^{\top}}{P_{k}^{(2)^{\top}}} A A P_{k}^{(1)}  \tag{44}\\
& -P_{k-1} P_{k-1}^{\top} A A P_{k}^{(1)} \\
= & A P_{k}^{(1)}-P_{k}^{(1)} P_{k}^{(1)^{\top}} A A P_{k}^{(1)}  \tag{45}\\
& -P_{k}^{(2)} P_{k}^{(2)^{\top}} A A P_{k}^{(1)}-P_{k-1} P_{k-1}^{\top} A A P_{k}^{(1)}
\end{align*}
$$

and $P_{k+1} U_{k}^{(1)}$ have a smaller size than $P_{k+1}$. Furthermore, by construction $P_{k+1} U_{k}^{(1)}$ belongs to span ${ }^{\square}\left\{A P_{k}^{(1)}\right\}$ and is A-orthogonal to $P_{0}, P_{1}, \ldots, P_{k-1}, P_{k}^{(1)}, P_{k}^{(2)}$.

This allows us to define the new search directions the first time we reduce the size of the block but we need to generalize this idea when the size is reduced several times (possibly until it is equal to one).

To do so we denote $H$ the matrix formed by the removed search directions $P_{i}^{(2)}, i \in\{1, \ldots, n\}$. It is important to note that if $\alpha_{k}$ is full rank, then $P_{k}^{(2)}$ is empty. Thus the number of columns of $H$ is at most $t-1$ where $t$ is the initial block size. Indeed, the final block size is at least 1 which means that the columns of $H$ are the $t-1$ search directions removed. $P_{i}^{(1)}$ is formed by the search directions that are used at iteration $i$ if $\alpha_{i}$ is nearly rank deficient. In order to prove Proposition 2 we will use the following lemma.
Lemma 1 For all $k \in\{1, \ldots, n\}$ we have:

$$
\begin{equation*}
P_{k}^{(1)^{\top}} A P_{k}^{(2)}=0 \tag{46}
\end{equation*}
$$

## Proof 3

$$
\begin{align*}
P_{k}^{(1)^{\top}} A P_{k}^{(2)} & =U_{k}^{(1)^{\top}} P_{k}^{\top} A P_{k} U_{k}^{(2)}  \tag{47}\\
& =U_{k}^{(1)}{ }^{\top} U_{k}^{(2)}  \tag{48}\\
& =0 \tag{49}
\end{align*}
$$

We want to construct $P_{k+1}$ such that:

$$
\begin{equation*}
P_{k+1}^{\top} A P_{i}^{(d)}=0, i<k+1, d=\{1,2\}, \tag{50}
\end{equation*}
$$

and $P_{k+1} \in \operatorname{span}^{\square}\left\{A P_{k}^{(1)}\right\}$.
One way to achieve this is to use Proposition 2. It leads to a variant of Orthodir where the number of search directions can be reduced dynamically during the iterations (Algorithm 3).

Another possibility is to use Proposition 3. Unlike Proposition 2 the new search directions are constructed using Orthomin instead of Orthodir (Algorithm 4). But it also allows to reduce the number of search directions dynamically during the iterations.

Proposition 2 If we define $P_{k+1}$ such that,

$$
\begin{align*}
P_{0}= & 0  \tag{51}\\
P_{1}= & A \text {-orthonormalize }\left(R_{0}\right)  \tag{52}\\
P_{k+1}= & A P_{k}^{(1)}-P_{k}^{(1)} P_{k}^{(1)^{\top}} A A P_{k}^{(1)}  \tag{53}\\
& -P_{k-1}^{(1)} P_{k-1}^{(1)} A A P_{k}^{(1)}-H H^{\top} A A P_{k}^{(1)} .
\end{align*}
$$

Then it is such that,

$$
\begin{equation*}
P_{k+1}^{\top} A P_{i}^{(d)}=0, i \leq k, d=\{1,2\} . \tag{54}
\end{equation*}
$$

Proof 4 The proof is based on induction on $k$.

- If $k \in\{0,1\}$ the descent directions $P_{k}$ are the same as in the usual Block Conjugate Gradient and (54) is true.
- If $k \in\{2, \ldots, n\}$ we assume that (54) is true for $k$ and $P_{i}^{(1)}, i \leq k$. We want to prove that it remains true for $P_{k+1}$. For all $i \leq k, d=\{1,2\}$ we have:

$$
\begin{align*}
P_{i}^{(d)}{ }^{\top} A P_{k+1} & =P_{i}^{(d)^{\top}} A A P_{k}^{(1)}  \tag{55}\\
& -P_{i}^{(d)^{\top}} A P_{k}^{(1)} P_{k}^{(1)}{ }^{\top} A A P_{k}^{(1)}  \tag{56}\\
& -P_{i}^{(d)}{ }^{\top} A P_{k-1}^{(1)} P_{k-1}^{(1)} A A P_{k}^{(1)}  \tag{57}\\
& -P_{i}^{(d)}{ }^{\top} A H H^{\top} A A P_{k}^{(1)} \tag{58}
\end{align*}
$$

- If $d=1$ then (58) is vanishing because $P_{i}^{(1)}{ }^{\top} A P_{l}^{(2)}=0$ : whether because $i \neq l$, or they are equal and we can use Lemma (1) to conclude that $P_{i}^{(1)^{\top}} A P_{i}^{(2)}=0$. If $i=k$ then (57) is equal to zero and (56) can be rewritten as:

$$
\begin{equation*}
P_{k}^{(d)^{\top}} A P_{k}^{(1)} P_{k}^{(1)^{\top}} A A P_{k}^{(1)}=P_{k}^{(1)^{\top}} A A P_{k}^{(1)} \tag{59}
\end{equation*}
$$

So (55) $=(56)$ and it follows that (54) is true. The same reasoning holds if $i=k-1$. If $k \leq k-2$ then (56) and (57) vanish. It remains to show that (55) is equal to zero. This is true because by construction $P_{k}^{(1)}$ is $A$-orthogonal to span ${ }^{\square}\left\{P_{0}, P_{1}, \ldots, P_{k-1}^{(1)}, H\right\}$ so $P_{i}^{(d)}{ }^{\top} A A P_{k}^{(1)}=0$. Hence (54) is true.

- If $d=2$ then (56) and (57) are vanishing because whether $i \leq k-2$, or $i \in\{k-1, k\}$ and we can use Lemma (1) to conclude. But if $d=2$ this means that we reduced the size at iteration $i$ and consequently (58) can be rewritten as:

$$
\begin{align*}
P_{i}^{(2)^{\top}} A H H^{\top} A A P_{k}^{(1)} & =P_{i}^{(2)^{\top}} A P_{i}^{(2)} P_{i}^{(2)^{\top}} A A P_{k}^{(1)}  \tag{60}\\
& =P_{i}^{(2)}{ }^{\top} A A P_{k}^{(1)} \tag{61}
\end{align*}
$$

So $(55)=(58)$ and it follows that (54) is true.

```
Algorithm 3 Orthodir with block size reduction
H
Require: \(A, B, X_{0}, k_{\text {max }}, \varepsilon_{\text {solver }}, \varepsilon_{\text {def }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)

        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(\left[U_{k}, \Sigma_{k}, V_{k}\right]=\operatorname{svd}\left(\alpha_{k}\right)\)
        \(s_{k}=\) number of singular values of \(\alpha_{k}\) bigger than \(\varepsilon_{\text {def }}\)
        if \(s_{k}<s_{k-1}\) then
            \(U_{k}^{(1)}=U_{k}\left(:, 1: s_{k}\right)\)
            \(U_{k}^{(2)}=U_{k}\left(:, s_{k}+1: e n d\right)\)
            \(\Sigma_{k}^{(1)}=\Sigma_{k}\left(1: s_{k}, 1: s_{k}\right)\)
            \(V_{k}^{(1)}=V_{k}\left(:, 1: s_{k}\right)\)
            \(P_{k}^{(2)}=P_{k} U_{k}^{(2)}\)
            \(H=\left[H, P_{k}^{(2)}\right]\)
            \(\alpha_{k}=\Sigma_{k}^{(1)} V_{k}^{(1)^{\top}} \quad \triangleright\) Reduce \(\alpha_{k}\) size
            \(P_{k}=P_{k} U_{k}^{(1)} \quad \triangleright\) Reduce \(P_{k}\) size
        end if
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(P_{k+1}=A P_{k}-P_{k} P_{k}^{\top} A A P_{k}-P_{k-1} P_{k-1}^{\top} A A P_{k}-H H^{\top} A A P_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

Proposition 3 Let $P_{k+1}$ be defined such that,

$$
\begin{align*}
P_{0} & =0,  \tag{62}\\
P_{1} & =A \text {-orthonormalize }\left(R_{0}\right),  \tag{63}\\
P_{k+1} & =R_{k}-P_{k}^{(1)} P_{k}^{(1)^{\top}} A R_{k} . \tag{64}
\end{align*}
$$

Then it is such that,

$$
\begin{equation*}
P_{k+1}^{\top} A P_{i}^{(d)}=0, i \leq k, d=\{1,2\} . \tag{65}
\end{equation*}
$$

Proof 5 The proof is by induction on $k$.

- If $k \in\{0,1\}$ the descent directions $P_{k}$ are the same as in the usual Block Conjugate Gradient and (65) is true.
- If $k \in\{2, \ldots, n\}$ we assume that (65) is true for $k$ and $P_{i}^{(1)}, i \leq k$. We want to prove that it remains true for $P_{k+1}$. For all $i \leq k, d=\{1,2\}$ we have:

$$
\begin{align*}
P_{i}^{(d)}{ }^{\top} A P_{k+1} & =P_{i}^{(d)^{\top}} A R_{k}  \tag{66}\\
& -P_{i}^{(d)}{ }^{\top} A P_{k}^{(1)} P_{k}^{(1){ }^{\top}} A R_{k}
\end{align*}
$$

- If $(i, d) \neq(k, 1)$ then,

$$
\begin{align*}
P_{i}^{(d)^{\top}} A P_{k+1} & =P_{i}^{(d)^{\top}} A R_{k}  \tag{67}\\
& =0, \tag{68}
\end{align*}
$$

by construction of $R_{k}$.

- If $(i, d)=(k, 1)$ then,

$$
\begin{align*}
P_{i}^{(d)^{\top}} A P_{k+1} & =P_{k}^{(1)^{\top}} A R_{k}-P_{k}^{(1)^{\top}} A R_{k}  \tag{69}\\
& =0 . \tag{70}
\end{align*}
$$

If $\alpha_{k+1}=P_{k+1}{ }^{\top} R_{k}$ is nearly rank deficient then we replace it by its low rank approximation and $P_{k+1}^{(1)}=P_{k+1} U_{k+1}^{(1)}$ and $P_{k+1}^{(2)}=P_{k+1} U_{k+1}^{(2)}$. Otherwise the size is not reduced and $P_{k+1}^{(2)}$ is empty.

## 5 Deflation tolerance

In this section we study the choice of the deflation tolerance in Algorithms 3 and 4. Let us recall that in [25] the authors show that $\|Z\|_{2} \leq\| \| A^{-1} \|_{2}^{1 / 2}$ if $Z$ is A-orthonormal. It is interesting to note that,

$$
\begin{align*}
\left\|\alpha_{k}\right\|_{2} & =\left\|P_{k+1}^{\top} R_{k}\right\|_{2}  \tag{71}\\
& \leq\left\|P_{k+1}\right\|_{2}\left\|R_{k}\right\|_{2}  \tag{72}\\
& \leq\left\|A^{-1}\right\|_{2}^{1 / 2}\left\|R_{k}\right\|_{2} \tag{73}
\end{align*}
$$

Hence, the following proposition holds.
Proposition 4 If we choose $\varepsilon_{\text {def }}$ such that

$$
\begin{equation*}
\varepsilon_{\text {def }}<\left\|A^{-1}\right\|_{2}^{1 / 2} \varepsilon_{\text {solver }}\|B\|_{2} \tag{74}
\end{equation*}
$$

then in exact arithmetic, Algorithms 3 and 4 are equivalent to their static counterpart Algorithms 2 and 1.

```
Algorithm 4 Orthomin with block size reduction
H
Require: \(A, B, X_{0}, k_{\max }, \varepsilon_{\text {solver }}, \varepsilon_{\text {def }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)
    \(P_{0}=0\)
    \(P_{1}=\) A-orthonormalize \(\left(R_{0}\right)\)
    \(k=1\)
    while \(\left\|R_{k-1}\right\|<\varepsilon_{\text {solver }}\|B\|\) and \(k<k_{\max }\) do
        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(\left[U_{k}, \Sigma_{k}, V_{k}\right]=\operatorname{svd}\left(\alpha_{k}\right)\)
        \(s_{k}=\) number of singular values of \(\alpha_{k}\) bigger than \(\varepsilon_{\text {def }}\)
        if \(s_{k}<s_{k-1}\) then
            \(U_{k}^{(1)}=U_{k}\left(:, 1: s_{k}\right)\)
            \(\Sigma_{k}^{(1)}=\Sigma_{k}\left(1: s_{k}, 1: s_{k}\right)\)
            \(V_{k}^{(1)}=V_{k}\left(:, 1: s_{k}\right)\)
            \(\alpha_{k}=\Sigma_{k}^{(1)} V_{k}^{(1)^{\top}} \triangleright\) Reduce \(\alpha_{k}\) size
            \(P_{k}=P_{k} U_{k}^{(1)} \quad \triangleright\) Reduce \(P_{k}\) size
        end if
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(P_{k+1}=R_{k}-P_{k}^{\top} P_{k} A R_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

Proof 6 If $\alpha_{k}$ does not loose full rank then it is clear that the proposition is true. On the other hand, if $\alpha_{k}$ is rank deficient, using Theorem 1, there exits $v \in \mathbb{R}^{n}$ such that for all $k \geq k^{*}$,

$$
\begin{equation*}
\left\|E_{k} v-E_{k-1} v\right\|_{A} \leq \varepsilon_{d e f} . \tag{75}
\end{equation*}
$$

And,

$$
\begin{equation*}
\left\|E_{k} v-E_{k-1} v\right\|_{A} \geq\left\|A^{-1}\right\|_{2}^{1 / 2}\left\|E_{k} v-E_{k-1} v\right\|_{2} \tag{76}
\end{equation*}
$$

Putting the two inequations together,

$$
\begin{align*}
\left\|E_{k} v-E_{k-1} v\right\|_{2} & \leq\left\|A^{-1}\right\|_{2}^{-1 / 2} \varepsilon_{\text {def }}  \tag{77}\\
& \leq \varepsilon_{\text {solver }}\|B\|_{2} \tag{78}
\end{align*}
$$

This means that $X_{k} v$ has already converged at the required tolerance. Hence, this part of the solution will remain constant during the following iterations.

Corollary 1 In Algorithms 3 and 4, if 74 is verified, the number of search directions used at iteration $k$, denoted $s_{k}$, is decreasing, i.e. $1 \leq s_{k+1} \leq s_{k} \leq t$ $\forall k \in\{1, \ldots, n\}$.
Proof 7 As stated in the proof of Proposition 4, $X_{k} v$ has already converged when removing the search directions related to $v$ for all the following iterations. As the size $s_{k}$ corresponds to $t$ minus the number of such vectors $v$. It remains to show that $s_{k}$ is always larger than 1. Let us assume that it is zero. Then we would have $\left\|\alpha_{k}\right\|_{2}=\varepsilon_{\text {def }}$ and if 74 is verified then the method would have converged.

Remark 1 In Algorithms 3 and 4 the converged solution is at most $\varepsilon_{\text {solver }}$ accurate even if we perform more iterations after the stopping criterion. After reducing the size we cannot expect higher accuracy than $\varepsilon_{\text {solver }}$ because we removed some information based on $\varepsilon_{\text {solver }}$ which is fixed a priori in the method. In other words, if $\varepsilon_{\text {def }}$ is too large the method will not converge (and if it is too small the number of search directions will not decrease).
Proof 8 This is a direct application of Theorem 1. Once we removed search directions we cannot recover them because we construct the new one by $A$ orthonormalizing against all previous ones.
Remark 2 The space $\mathcal{K}_{k}^{\triangle}$ is not exactly the same as $\mathcal{K}_{k}^{\square}$. In fact, it is smaller because some of the search directions have been removed. Even if Proposition 4 is true in exact arithmetic, due to round-off errors during orthonormalization we are expecting to do (hopefully not many) more iterations when reducing the size.

Proposition 5 When using the block Conjugate Gradient to solve a linear system with a single right hand side, the following deflation criterion ensures that the methods with dynamic reduction of the search directions are equivalent in exact arithmetic to their static counterpart,

$$
\begin{equation*}
\varepsilon_{\text {def }}<\frac{1}{\sqrt{t}}\left\|A^{-1}\right\|_{2}^{1 / 2} \varepsilon_{\text {solver }}\|b\|_{2} \tag{79}
\end{equation*}
$$

Proof 9 When solving a system with a single right hand side,

$$
\begin{align*}
\left\|r_{k}\right\|_{2} & =\left\|R_{k} \mathbb{1}_{t}\right\|_{2}  \tag{80}\\
& \leq\left\|R_{k}\right\|_{2}\left\|\mathbb{1}_{t}\right\|_{2}  \tag{81}\\
& \leq\left\|R_{k}\right\|_{2} \sqrt{t} \tag{82}
\end{align*}
$$

Hence,

$$
\begin{align*}
\left\|\alpha_{k}\right\|_{2} & \leq\left\|A^{-1}\right\|_{2}^{1 / 2}\left\|R_{k}\right\|_{2}  \tag{83}\\
& \leq \frac{1}{\sqrt{t}}\left\|A^{-1}\right\|_{2}^{1 / 2}\left\|r_{k}\right\|_{2}  \tag{84}\\
& \leq \frac{1}{\sqrt{t}}\left\|A^{-1}\right\|_{2}^{1 / 2} \varepsilon_{\text {solver }}\|b\|_{2} \tag{85}
\end{align*}
$$

The rest of the proof is exactly the same as in the one of Proposition 4.
Remark 3 In practice, it is too costly to compute the optimal criteria in (74) and (79). But it is easy to see that if,

$$
\begin{equation*}
\left\|A^{-1}\right\|_{2}^{1 / 2} \geq 1 \tag{86}
\end{equation*}
$$

then we can use,

$$
\begin{equation*}
\varepsilon_{\text {def }}=\varepsilon_{\text {solver }}\|b\|_{2} \tag{87}
\end{equation*}
$$

instead of 74, and,

$$
\begin{equation*}
\varepsilon_{d e f}=\frac{1}{\sqrt{t}} \varepsilon_{\text {solver }}\|b\|_{2} \tag{88}
\end{equation*}
$$

instead of 79.
In all the numerical experiments, the criterion for removing the number of search directions is 88 .

## 6 Numerical results

All the results are obtained with Matlab R2015b. PCG is the Matlab Preconditioned Conjugate Gradient method. We always use a splitted block Jacobi preconditioner and we refer to nj as the number of diagonal blocks used.

We compare the performance of the three methods on a set of matrices that are also used in $[8,21,22]$ where they are described in more details. These matrices are displayed in Table 1 where we present their size, the number of nonzeros, their smallest and largest eigenvalues. The matrices NH2D, SKY2D, SKY3D and ANI3D arise from boundary value problem of the diffusion equations:

$$
\begin{align*}
-\operatorname{div}(\kappa(x) \nabla u) & =f & & \text { on } \Omega  \tag{89}\\
u & =0 & & \text { on } \partial \Omega_{D} \\
\frac{\partial u}{\partial n} & =0 & & \text { on } \partial \Omega_{N} \tag{90}
\end{align*}
$$

where $\Omega$ is the unit square (2D) or cube (3D). The tensor $\kappa$ is a given coefficient of the partial differential operator. In the 2D case $\partial \Omega_{D}=[0,1] \times\{0,1\}$ and in the 3D case $\partial \Omega_{D}=[0,1] \times\{0,1\} \times[0,1]$. In both cases, $\partial \Omega_{N}$ is choosen as $\partial \Omega_{N}=\partial \Omega \backslash \partial \Omega_{D}$.

The matrix NH2D is obtained by considering a nonhomogeneous problem with large jumps in the coefficients of $\kappa$. The tensor $\kappa$ is isotropic and discontinuous, it jumps from the constant value $10^{3}$ in the ring $\frac{1}{2 \sqrt{2}} \leq|x-c| \leq \frac{1}{2}$ with $c=\left(\frac{1}{2}, \frac{1}{2}\right)^{\top}$, to 0 outside.

The matrices SKY2D and SKY3D are obtained by considering skyscraper problems where the domain contains many zones of high permeability wich are isolated from each other. More precisely $\kappa$ is taken as:

$$
\begin{array}{lr}
\kappa(x)=10^{3} *\left(\left[10 * x_{2}\right]+1\right) & \text { if }\left[10 x_{i}\right] \text { is odd, } i=\{1,2\} \\
\kappa(x)=1 & \text { otherwise }, \tag{93}
\end{array}
$$

where $[x]$ is the integer value of $x$.
The matrix ANI3D is obtained by considering anisotropic layers: the domain is made of 10 anisotropic layers with jumps of up to four orders of magnitude and an anisotropy ratio of $10^{3}$ in each layer. Those layers are parallel to $z=0$, of size 0.1 , and inside them the coefficients are constant: $\kappa_{y}=10 \kappa_{x}, \kappa_{z}=100 \kappa_{x}$.

All those problemes are discretized on cartesian grids, of size $100 \times 100$ for the 2 D problems and of size $20 \times 20 \times 20$ for the 3 D problems.

The Ela matrices arise from the linear elasticity problem with Dirichlet and Neumann boundary conditions defined as follows

$$
\begin{align*}
\operatorname{div}(\sigma(u))+f & =0 & & \text { on } \Omega  \tag{94}\\
u & =0 & & \text { on } \partial \Omega_{D}  \tag{95}\\
\sigma(u) \cdot n & =0 & & \text { on } \partial \Omega_{N} \tag{96}
\end{align*}
$$

$\Omega$ is a unit square (2D) or cube (3D). The matrices Ela $N$ correspond to this equation discretized using a triangular mesh with $N \times 10 \times 10$ points on the corresponding vertices. The matrices Ela2D $N$ correspond to this equation discretized unsing a triangular mesh with $N \times N$ points on the corresponding vertices. $\partial \Omega_{D}$ is the Dirichlet boundary, $\partial \Omega_{N}$ is the Neumann boundary, $f$ is some body force, $u$ is the unknown displacement field. $\sigma($.$) is the Cauchy stress$ tensor given by Hooke's law: it can be expressed in terms of Young's Modulus $E$ and Poisson's ration $\nu$. For a more detailed description of the problem see [23] and [9]. We consider discontinuous $E$ and $\nu$ in 3D: $\left(E_{1}, \nu_{1}\right)=\left(2 \times 10^{11}, 0.25\right)$ and $\left(E_{2}, \nu_{2}\right)=\left(10^{7}, 0.45\right)$; and discontinuous $E$ in 2D were the fluid is nearly incompressible: $\left(E_{1}, \nu_{1}\right)=\left(10^{12}, 0.45\right)$ and $\left(E_{2}, \nu_{2}\right)=\left(2 \times 10^{6}, 0.45\right)$. Those matrices are scaled in order to reduce the effect of possibly very high values on the diagonal.

Table 1: Test matrices we use in our tests, their size, the number of nonzeros, their smallest $\left(\lambda_{\min }\right)$ and largest ( $\lambda_{\min }$ ) eigenvalues; if they are coming from 2D or 3D discretization and the type of problem they are coming from.

|  | Size | Nonzeros | $\lambda_{\min }$ | $\lambda_{\max }$ | 2D/3D | Problem |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |

Table 2: Numerical parameters we consider in our tests, the size of the initial block (which is also the number of right hand sides), the number of diagonal blocks nj in the block diagonal preconditioner, the variant we use between Orthomin and Orthodir, the definition of the error and the number of iterations..

| t | block size |
| :---: | :--- |
| nj | number of block Jacobi |
| Odir | Orthodir |
| Omin | Orthomin |
| er | $\frac{\left\\|x^{*}-x_{k}\right\\|_{2}}{\left\\|x^{*}\right\\|_{2}}$ with $x^{*}$ the exact solution (computed with Matlab LU) |
| iter | number of iterations until convergence |

In Table 3 we summarize the results obtained when running Orthomin (Algorithm 1) and Orthodir (Algorithm 2) on the same matrix for BRRHS-CG [7], Coop-CG [6], and EK-CG [8]. We denote Omin1 the version where we use A-CholQR (Algorithm 5) to A-orthonormalize the search directions block and Omin2 the version where we use Pre-CholQR (Algorithm 6). We also compare with Matlab PCG method. We observe that breakdowns happen with Omin1 when the matrix is very ill-conditioned (Ela100). Omin2 may perform $30 \%$ more iterations than Orthodir on difficult matrices (Ela50 and Ela100) but they are equivalent on simple test cases (NH2D, SKY2D, SKY3D, ANI3D) and there is no breakdowns unlike Omin1. In all the following experiments we always use Omin2 and denote it as Omin.

Table 3: Number of iterations to get the solution $\left(\varepsilon_{\text {solver }}=10^{-8}\right)$, the stopping criterion is the error, i.e. $\frac{\left\|x^{*}-x_{k}\right\|_{2}}{\left\|x^{*}\right\|_{2}}$ where $x^{*}$ is the exact solution computed with LU. Omin2 and Odir are equivalent on NH2D, SKY2D, SK3D and ANI3D but on elasticity test cases (Ela50 and Ela100) Odir is more stable than Omin2. Omin1 is the less stable because breakdowns can occur on difficult matrices.

The results presented in Table 4 compare the classical PCG, BRRHS-CG, and EK-CG on several matrices from our test set. In the first three columns we present experiments where we increase both the number of block Jacobi nj and the block size $t$ while keeping their ratio constant. As the number of block Jacobi increases, the preconditioner becomes less effective. Our goal is to compensate this by an increase of the block size so that the number of iterations does not increase or even decreases. The corresponding results are summerized in the first columns of Table 4. In all the cases considered, BRRHS-CG and EK-CG behave very similarly: the number of iterations is almost the same for both methods. When the block size increases, and even if the preconditioner is less effective, the block methods can drastically reduce the number of iterations with respect to PCG (except for ANI3D for which we observe that the iteration count obtained with 2 vectors in the block is reduced by a factor 2 and up to 3 when 32 vectors are used in the block). Furthermore, the block methods are very effective in comparison with PCG. This is especially true when the block size is large (a factor more than 2 and up to more than 10). But even for small block sizes we can observe a significant gain, nearly a factor of 2 for the elasticity matrices for example.

The last three column in Table 4 present results obtained when the block size is increased while the number of blocks nj in the block Jacobi preconditioner is kept constant. The corresponding results are summerized in the last 4 columns of Table 4. In this case we expect that the number of iterations will decrease because the preconditioner is the same but the block size increases, so the search space grows faster with larger block size. And this is what we obtain. For almost all matrices (except ANI3D) we observe a gain of a factor between 3 and 10 in terms of iteration count. However, for several matrices up to a certain block size the gain is not significant anymore (NH2D and SKY2D for example). As in the previous experiment, BRRHS-CG and EK-CG behave very similarly in terms of iteration count.

Table 4: Number of iterations to get the solution $\left(\varepsilon_{\text {solver }}=10^{-8}\right)$ with Orthodir (Algortihm 2, and PCG is the usual Preconditioned Conjugate Gradient), the stopping criterion is the error, i.e. er $=\frac{\left\|x^{*}-x_{k}\right\|_{2}}{\left\|x^{*}\right\|_{2}}$ where $x^{*}$ is the exact solution computed with LU.

The results in Table 5 show a comparison between BRRHS-CG, Coop-CG and EK-CG with (Algorithm 2) and without reducing the block size (Algorithm $3)$. We observe that our method to reduce the block size is stable in practice: the number of iterations with or without the block size reduction is of the same order, and still far lower than with the usual PCG method. More precisely the gain is between $22 \%$ less iterations for ANI3D test case, and up to a factor of 17 for the quasi incompressible elasticity test case. For most of the test cases, the block methods perform 5 to 15 less iterations than the usual PCG even when the block size is reduced. However, it is effective because the dimension of the search space (denoted $\mathcal{K}_{k}^{\triangle}$ ) is well decreased. For the test cases where the number of iteration is relatively small (as in NH2D, SKY2D, SKY3D and

## H

Table 5: Number of iterations to get the solution with Orthodir with dynamic reduction of the search directions (Algorithm 3, $\varepsilon_{\text {solver }}=10^{-6}$ and $\varepsilon_{\text {def }}=\varepsilon_{\text {solver }}\|b\|_{2}-\varepsilon_{\text {machine }}$ for BRRHS-CG and Coop-CG, and $\varepsilon_{\text {def }}=\frac{\varepsilon_{\text {solver }}\|b\|_{2}}{\sqrt{t}}$ for EK-CG), the stopping criterion is the normalized residual. The initial the block size is 32 and the number of block Jacobi is 1024 . The symbol $\checkmark$ means that we reduced the size of the block and $\times$ means that we used the usual algorithm.

ANI3D test cases), the dimension of the search space is descreased by around $10 \%$. But for the more complex test cases as elasticity test cases, the dimension of the search space is reduced between $20 \%$ and $30 \%$. For those test cases, EK-CG performs very well. The final search space is smaller but the number of iterations is still very low. For the Ela100 test case, the search space of EK-CG is around $25 \%$ smaller than the final one of BRRHS-CG and Coop-CG, and the number of iterations is about $10 \%$ higher than BRRHS-CG, but around $10 \%$ lower than Coop-CG.

In Figure 2, we plot the error (left), as well as the size of the block (right), as a function of the number of iterations for SKY2D and Ela100. We consider that the initial block size is 32 and the number of blocks nj in the block Jacobi preconditioner is 1024 . For both matrices, we observe that the convergence of the error is far better for the block methods compared to PCG even with the block size reduction (a factor of 7 for SKY2D and 10 for Ela100). Still there is a small plateau before convergence for all the methods which is a well known phenomenon with Krylov methods [10, 18]. The block size reduction and the error behave similarly for both matrices, the block size is reduced when the system is starting to converge (around iteration 40 for SKY2D and iteration 60 for Ela100). For the two test cases, EK-CG performs better than Coop-CG and BRRHS-CG, it reduces its search directions faster than Coop-CG and better than BRRHS-CG. For these tests, unlike Coop-CG and EK-CG, BRRHS-CG final block size is greater than 1. But it keeps a convergence speed similar as the one of BRRHS-CG, and always faster than the one of Coop-CG.

Figure 2: Block size reduction and error decreasing as a function of the number of iterations when using Orthodir with dynamic reduction of the search directions (Algorithm 3). The right figures represent the plot of the error as a function of the number of iterations. We use a $\log _{10}$ scale for the error. The left figures represent the plot of the block size as a function of the number of iterations. We only plot the block size for the block methods and not for PCG.

In short, the results in Table 5 and Figure 2 show that EK-CG finds the solution of the linear system in a smaller subspace than the other block methods considered (BRRHS-CG and Coop-CG) when reducing the search directions with Algorithm 3.

The results in Table 6 show a comparison between BRRHS-CG, Coop-CG and EK-CG with (Algorithm 1) and without reducing the block size (Algorithm 4). In that case we observe that our method to reduce the block size is not always stable in practice. Although the number of iterations for NH2D, SKY2D, SKY3D and ANI3D is almost the same when reducing or not the number of search directions, it is not the case for elasticity matrices where the reduction can lead to very slow convergence. However, for the matrices NH2D, SKY2D, SKY3D and ANI3D we observe the similar behaviour as with Algorithm 3. The blocks methods converge faster with or without reducing the number of search

## H

Table 6: Number of iterations to get the solution with Orthomin with dynamic reduction of the search directions (Algorithm 4, $\varepsilon_{\text {solver }}=10^{-6}$ and $\left.\varepsilon_{\text {def }}=\frac{\varepsilon_{\text {solver }}\|b\|_{2}}{\sqrt{t}}\right)$, the stopping criterion is the nomalized residual. directions are faster than PCG (between 5 and 6 times less iterations for SKY3D for example). For all those matrices (NH2D, SKY2D, SKY3D and ANI3D) EKCG achieves both a fast convergence in terms of iterations and a good reduction of the search space. For example, for ANI3D when reducing the size EK-CG and BRRHS-CG have the same iteration count but the search space of EK-CG is around $10 \%$ smaller. For elasticity matrices, even if the method seems to converge (which is prooved in theory for the deflation criterion we choosed), the convergence is very slow in terms of iterations. Extra numerical experiments suggest that this is due to the loss of othogonality. Indeed, we tried to Aorthonormalize $P_{k+1}$ against $P_{k}^{(2)}$ explicitely and this decreases the number of iterations. However, it is not possible to do it in practice because the extra cost in terms of flops and communications would prevent any improvement in terms of performance compared to Orthomin without dynamical reduction of the search directions.

## 7 Conclusion

Starting from block Conjugate Gradient [3], we expressed a familly of methods for solving symmetric positive definite systems. A first difference is the method for constructing the search directions. Orthomin is the original method presented in [3], it follows the original Conjugate Gradient of Hestenes and Stiefel [5]. Following [8] it is also possible to construct the search directions using Orthodir, this method is presented in [2] in the case of Conjugate Gradient.

Although Orthodir is twice as expensive as Orthomin, it has the advantages to be breakdown-free without needing to use Pre-CholQR (Algorithm 6). Even
if in theory they are equivalent if there is no breakdown, numerical results show that Orthodir is also more effective than Orthomin in terms of iterations on very ill-conditioned matrices.

We presented a method that allows to reduce dynamically the number of search directions during a block CG-like method. It is completely algebraic, and does not depend of the variant of block CG used (BRRHS-CG, CoopCG, EK-CG), nor the formula for constructing the search directions (Orthomin or Orthodir). We also proposed a practical tolerance that ensures (in exact arthmetic) the equivalence of our method with the case where the number of search directions is not reduced. Numerical experiments show that the method used with Orthodir (Algorithm 3) is both stable, the number of iterations with or without the reduction of the number of search directions is of the same order, and effective, the search space is reduced from $10 \%$ and up to $30 \%$ in practice. However, the method used with Orthomin (Algorithm 4), is not stable on very ill-conditioned matrices. The number of iterations can dractically increase. On the other matrices, the behaviour of the method is almost the same as with Orthodir, and we observe that EK-CG is preferable compared to the other variants we studied because it allows to reduce the number of search directions effectively while maintaining a good convergence speed.

To conclude, we estimate that Orthomin is, in general, more effective than Orthodir if the matrix is not very ill-conditioned because it is equivalent to Orthodir but twice as cheap both in terms of flops and communication. For very ill-conditioned matrices, Orthodir with reduction of the number of search directions is more stable. As future work, the methods will be implemented in parallel and their performance will be evaluated on massively parallel machines.

## Appendix A

The two following algorithms are described in [11]. The first one, A-CholQR (Algorithm 5) is a generalization of CholQR to the case of an oblique inner product. The second one, Pre-CholQR (Algorithm 6) is a more robust version of A-CholQR that adds an extra QR factorization at the beginning.

```
Algorithm 5 AChol-QR(P)
Require: P
Ensure: \(P^{\top} A P=\rrbracket_{t \times t}\)
    \(C=P^{\top} A P\)
    \(L=\operatorname{chol}(C)\)
    \(P=P / L\)
    for \(i=1: t\) do
        \(P^{(i)}=\frac{P^{(i)}}{\left\|P^{(i)}\right\|_{A}}\)
    end for
```

```
Algorithm 6 PreChol-QR(P)
Require: P
Ensure: \(P^{\top} A P=\square_{t \times t}\)
    \(P=Q R\)
    \(C=Q^{\top} A Q\)
    \(L=\operatorname{chol}(C)\)
    \(P=Q / L\)
    for \(i=1: t\) do
        \(P^{(i)}=\frac{P^{(i)}}{\left\|P^{(i)}\right\|_{A}}\)
    end for
```

## Appendix B

Following Saad [27], the idea for applying left preconditioning to Conjugate Gradient is to remark that $M^{-1} A$ is self-adjoint with respect to the $M$-inner product. It is possible to generalize this idea to the block case by remarking that,

$$
\begin{equation*}
X^{\top} A M^{-1} M Y=X^{\top} M M^{-1} A Y \tag{97}
\end{equation*}
$$

Hence, if we denote by $Z_{k}=M^{-1} R_{k}$ the residual for the preconditioned system, it is possible to rewrite the Algoritms 1 and 2 (ignoring the initial step) for the matrix $M^{-1} A$ using the M-inner product instead of the euclidean one,

$$
\begin{align*}
\alpha_{k} & =P_{k}^{\top} M Z_{k-1}=P_{k}^{\top} R_{k-1}  \tag{98}\\
X_{k} & =X_{k-1}+P_{k} \alpha_{k}  \tag{99}\\
R_{k} & =R_{k-1}-A P_{k} \alpha_{k}  \tag{100}\\
Z_{k} & =M^{-1} Z_{k} \tag{101}
\end{align*}
$$

Then it is possible to derive the Orthomin version as,

$$
\begin{align*}
P_{k+1} & =Z_{k}-P_{k} P_{k}^{\top} A M^{-1} M Z_{k}  \tag{102}\\
& =Z_{k}-P_{k} P_{k}^{\top} A Z_{k}, \tag{103}
\end{align*}
$$

or the Orthodir version as,

$$
\begin{align*}
P_{k+1} & =M^{-1} A P_{k}-P_{k} P_{k}^{\top} A M^{-1} M M^{-1} A P_{k}-P_{k-1} P_{k-1}^{\top} A M^{-1} M M^{-1} A P_{k}  \tag{104}\\
& =M^{-1} A P_{k}-P_{k} P_{k}^{\top} A M^{-1} A P_{k}-P_{k-1} P_{k-1}^{\top} A M^{-1} A P_{k} \tag{105}
\end{align*}
$$

To derive those relationships we assumed that, similarly to the unpreconditioned case, the block $P_{k}$ is $M^{-1} A$-orthonormal with respect to the M-inner product. More precisely,

$$
\begin{equation*}
P_{k}^{\top} M M^{-1} A P_{k}=P_{k}^{\top} A P_{k}=I \tag{106}
\end{equation*}
$$

Therefore, it is equivalent to A-orthonormalize the block $P_{k}$. Putting all thoses relationships together, it is possible to derive Algorithms 7 and 8.

```
Algorithm 7 Preconditioned Orthomin BCG
Require: \(A, M, B, X_{0}, k_{\max }, \varepsilon_{\text {solver }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)
    \(P_{1}=\) A-orthonormalize \(\left(M^{-1} R_{0}\right)\)
    \(k=1\)
    while \(\left\|R_{k-1}\right\|>\varepsilon_{\text {solver }}\|B\|\) and \(k<k_{\text {max }}\) do
        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(Z_{k}=M^{-1} R_{k}\)
        \(P_{k+1}=Z_{k}-P_{k} P_{k}^{\top} A Z_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

```
Algorithm 8 Preconditioned Orthodir BCG
Require: \(A, M, B, X_{0}, k_{\max }, \varepsilon_{\text {solver }}\)
Ensure: \(\|B-A X\|<\varepsilon_{\text {solver }}\) or \(k=k_{\max }\)
    \(R_{0}=B-A X_{0}\)
    \(P_{0}=0\)
    \(P_{1}=\) A-orthonormalize \(\left(M^{-1} R_{0}\right)\)
    \(k=1\)
    while \(\left\|R_{k-1}\right\|>\varepsilon_{\text {solver }}\|B\|\) and \(k<k_{\text {max }}\) do
        \(\alpha_{k}=P_{k}^{\top} R_{k-1}\)
        \(X_{k}=X_{k-1}+P_{k} \alpha_{k}\)
        \(R_{k}=R_{k-1}-A P_{k} \alpha_{k}\)
        \(Z_{k}=M^{-1} A P_{k}\)
        \(P_{k+1}=Z_{k}-P_{k} P_{k}^{\top} A Z_{k}-P_{k-1} P_{k-1}^{\top} A Z_{k}\)
        \(P_{k+1}=\) A-orthonormalize \(\left(P_{k+1}\right)\)
        \(k=k+1\)
    end while
```

Table 7: Number of iterations to get the solution $\left(\varepsilon_{\text {solver }}=10^{-6}\right)$, the stopping criterion is the error, i.e. er $=\frac{\left\|x^{*}-x_{k}\right\|_{2}}{\left\|x^{*}\right\|_{2}}$ where $x^{*}$ is the exact solution computed with LU . The comparison is between left or splitted preconditioner, and the results are the same for both.
