#### Abstract

The design of multi-stable RNA molecules has important applications in biology, medicine, and biotechnology. Synthetic design approaches largely benefit from effective in-silico methods, which can tremendously impact their cost and feasibility. Here, we revisit a central ingredient of most in-silico design methods: the sampling of sequences for multi-target design. We establish the \#P-hardness of uniform sampling, and introduce RNARedPrint, a tree decomposition-based algorithm for efficient, fixed parameter tractable sampling. By modeling the problem as a constraint network, RNARedPrint supports generic Boltzmann-weighted sampling for arbitrary additive RNA energy models; this enables generating designs meeting specific goals like expected free energies or GC-content. Finally, we empirically study general properties of the approach and generate biologically relevant multi-target Boltzmannweighted designs for a common design benchmark. In particular, we show significant improvements over seed sequences generated by uniform sampling, the previously best available sampling strategy for multi-target design. Our software is freely available at: https://github.com/yannponty/RNARedPrint

Keywords: Multi-target RNA Design, Counting Complexity, Boltzmann Sampling

## 1 Introduction

Synthetic biology endeavors the engineering of artificial biological systems, promising broad applications in biology, biotechnology and medicine. Centrally, this requires the design of biological macromolecules with highly specific properties and programmable functions. In particular, RNAs present themselves as well-suited tools for rational design targeting specific functions [21]. RNA function is tightly coupled to the formation of secondary structure, as well as changes in base pairing propensities and the accessibility of regions, e.g. by burying or exposing interaction sites [26]. At the same time, the thermodynamics of RNA secondary structure is well understood and its prediction is computationally tractable [24]. Thus, structure can serve as effective proxy within rational design approaches, ultimately targeting catalytic [33] or regulatory [26] functions.

The function of many RNAs depends on their selective folding into one or several alternative conformations. Classic examples include riboswitches, which notoriously adopt different stable structures upon binding a specific ligand. Riboswitches have been a popular application of rational design [30,11], partly motivated by their capacity to act as biosensors [13]. At the co-transcriptional level, certain RNA families feature alternative, evolutionarily conserved, transient structures [35], which facilitate the ultimate adoption of functional structures at full elongation. More generally, simultaneous compatibility to multiple structures is a relevant design objective for engineering kinetically controlled RNAs, finally targeting prescribed folding pathways. Thus, modern applications of RNA design often target (the simultaneous stability of) multiple structures, additionally aiming at other features, such as specific GC-content [25] or the presence/absence of functionally relevant motifs (either anywhere or at specific positions) [34]; these objectives motivate flexible computational design methods.

Many computational methods for RNA design rely on similar overall strategies: initially generating one or several seed sequences and optimizing them subsequently. In many cases, the seed quality was found to be critical for the empirical performance (and solution quality) of RNA design methods [22]. For instance, random seed generation improves the prospect of subsequent optimizations, helping to overcome local optima of the objective function, and induce better sequence diversity across designs [25]. For single-target approaches, INFO-RNA [5] made significant improvements mainly by starting its local search from the minimum energy sequence for the target structure instead of (uniform) random sequences for the early RNAinverse algorithm [19]. This strategy was later shown to result in unrealistically high GC-contents in designed sequences. To address this issue, IncaRNAtion [25] controls the GC-content through an adaptive sampling strategy.

Specifically, for multi-target design, virtually all available methods [23,18,27,17] follow the same overall generation/optimization scheme. Facing the complex sequence constraints induced by multiple targets, early methods such as Frnakenstein [23] and Modena [27] did not attempt to solve sequence generation systematically, but rely on $a d$-hoc sampling strategies. Recently, the RNAdesign approach [18], coupled with powerful local search within RNAblueprint [17], solved the problem of sampling seeds from the uniform distribution for multiple targets. These methods adopt a graph coloring perspective, initially decomposing the graph hierarchically using various decomposition algorithms, and precomputing the number of valid sequences within each subgraph. The decomposition is then reinterpreted as a decision tree to perform a stochastic backtrack, inspired by Ding and Lawrence [10], where individual assignments are chosen with probabilities derived from the subsolution counts, leading to uniform sampling. The overall complexity of RNAdesign grows like $\Theta\left(4^{\gamma}\right)$, where $\gamma$ is a parameter whose value is bounded only by the length of the designed RNA.

The exponential time and space requirements of the RNAdesign method already raise the question of the complexity of (uniform) sampling for multi-target design. Since stochastic backtrack can

Fig. 1: General outline of RNARedPrint for base pair-based energy models. From a set of target secondary structures (i), base-pairs are merged (ii) into a compatibility graph (iii) and transformed into a tree decomposition (iv). The tree is then used to compute the partition function, followed by a Boltzmann sampling of valid sequences (v). An adaptive scheme learns weights to achieve targeted energies and GC-content, leading to the production of suitable designs (vi).
be performed in linear time per sample, the method is dominated by the precomputation step, which requires counting valid designs. Thus, we focus on the question: Is there a polynomial-time algorithm to count valid multi-target designs? In Section 3, we answer in the negative, showing that there exists no such algorithm unless $P=N P$. Our result relies on a surprising bijection (up to a trivial symmetry) between valid sequences and independent sets of a bipartite graph, being the object of recent breakthroughs in approximate counting complexity [4,6]. The hardness of counting (and conjectured hardness of sampling) does not preclude, however, practically applicable algorithms for counting and sampling. In particular, we wish to extend the flexibility of multi-structure design, leading to the following questions: How to sample, in a principled way, from a Boltzmann distribution based on expressive energy models? How to enforce additional constraints, such as the GC-content, complex sequence constraints, or the energy of individual structures?

To answer these questions, we introduce a generic framework (illustrated in Fig. 1) enabling efficient Boltzmann-weighted sampling over RNA sequences with multiple target structures (Section 4). Guided by a tree decomposition of the network, we devise dynamic programming to compute partition functions and sample sequences from the Boltzmann distribution. We show that these algorithms are Fixed-Parameter Tractable for the treewidth; in practice, we limit this parameter by using state-of-the-art tree decomposition algorithms. By modeling sequences as variable assignments in a weighted constraint network, we support arbitrary multi-ary constraints and thus arbitrarily complex energy models, notably subsuming all commonly used RNA energy models. Moreover, we describe an adaptive sampling strategy to control the free energies of the individual target structures and the GC-content. Notably, the sampling procedure is based on a simplified RNA energy model, taking only the most important energy contributions into account, which crucially limits computation time and space; at the same time, our approach targets realistic RNA energies in the well-accepted Turner RNA energy model. This high accuracy enables efficiently generating biologically relevant multi-target designs in our final application of our overall strategy to a large set of multi-target RNA design instances from a representative benchmark Section 5).

## 2 Definitions and problem statement

An RNA sequence $S$ is a word over the nucleotides alphabet $\Sigma=\{\mathrm{A}, \mathrm{C}, \mathrm{G}, \mathrm{U}\} ;$ let $\mathcal{S}_{n}$ denote the set of sequences of length $n$. An RNA (secondary) structure of length $n$ is a set of base pairs $(i, j)$, where $1 \leq i<j \leq n$. We call an RNA structure $R$ non-crossing, iff it does not contain any two different base pairs $(i, j)$ and $\left(i^{\prime}, j^{\prime}\right)$ such that $i \leq i^{\prime} \leq j \leq j^{\prime}$. Valid base pair must pair bases from the $\mathcal{B}:=\{\{\mathrm{A}, \mathrm{C}\},\{\mathrm{G}, \mathrm{C}\},\{\mathrm{G}, \mathrm{U}\}\}$. Consequently, $S$ is valid for $R$, iff $\left(S_{i}, S_{j}\right) \in \mathcal{B}$ for all $(i, j) \in R$.

Given is a fixed set of target RNA structures $\mathcal{R}:=\left\{R_{1}, \ldots, R_{k}\right\}$ for sequences of length $n . \mathcal{R}$ induces a compatibility graph $G_{\mathcal{R}}$ with nodes $\{1, \ldots, n\}$ and edges $\bigcup_{\ell \in[1, k]} R_{\ell}$. Valid sequences for $\mathcal{R}$ can then be seen as specific colorings of $G_{\mathcal{R}}$, using the four colors in $\Sigma$, such that the colors assigned to adjacent vertices of $G_{\mathcal{R}}$ constitute valid base pairs. We define the energy of a sequence $S$ based on the set of structures $\mathcal{R}$ as $E_{\mathcal{R}}(S) \in \mathbb{R} \cup\{\infty\}$. In our setting, the energy $E_{\mathcal{R}}(S)$ is additively composed of the energies of the single RNA structures in an RNA energy model, as well as sequence dependent features like GC-content. Furthermore note that $E_{\mathcal{R}}(S)$ is finite iff $S$ is valid for each structure $R_{1}, \ldots, R_{k}$.

At the core of this work, we study the computation of partition functions over sequences.
Central problem (Partition function over sequences). Given an energy function $E$ and a set $\mathcal{R}$ of structures of length $n$, compute the partition function

$$
\begin{equation*}
\mathcal{Z}_{E_{\mathcal{R}}}(S)=\sum_{S \in \mathcal{S}_{n}} \exp \left(-\beta E_{\mathcal{R}}(S)\right), \tag{1}
\end{equation*}
$$

where $\beta$ denotes the inverse pseudo-temperature, and $\mathcal{S}_{n}$ the set of sequences of length $n$.
As will be explicited in future sections, our approach relies on breaking down the energy function $E_{\mathcal{R}}(S)$ into additive components, each depending on only few sequence positions. Given $\mathcal{R}$, we express $E_{\mathcal{R}}(S)$ as the sum of energy contributions $f(S)$ over a set $\mathcal{F}$ (of functions $f: \mathcal{S}_{n} \rightarrow$ $\mathbb{R}$ ), s.t. $E_{\mathcal{R}}(S)=\sum_{f \in \mathcal{F}} f(S)$. This captures realistic RNA energy models, while bounding the dependencies to sequence positions introduced by each single $f$. Formally, define the dependencies $\operatorname{dep}(f)$ of $f$ as the minimal set of sequence positions $\mathcal{I} \subseteq\{1, \ldots, n\}$, where $f(S)=f\left(S^{\prime}\right)$ for all sequences $S$ and $S^{\prime}$ agreeing at all positions in $\mathcal{I}$.

The dependency graph of the set $\mathcal{F}$ of functions (on sequences of length $n$ ) is the hypergraph $G_{\mathcal{F}}=(\{1, \ldots, n\},\{\operatorname{dep}(f) \mid f \in \mathcal{F}\})$. Our algorithms will critically rely on a tree decomposition of the dependency graph, which we define below.

Definition 1 (Tree decomposition and width). Given an hypergraph $G=(X, E), a$ tree decomposition is a pair $(T, \chi)$, where $T$ is an unrooted tree/forest, and $\chi(v) \subseteq X$ is the set of vertices from $G$ assigned to the node $v \in T$, such that

1. each $x \in X$ occurs in at least one $\chi(v)$;
2. for each $x \in X$, the set $\{v \mid x \in \chi(v)\}$ induces a connected subtree of $T$.
3. for every hyper-edge $e \in E$ of $G$, there is a node $v \in T$, such that $e \subseteq \chi(v)$.

The width of a tree decomposition $(T, \chi)$ is defined as $w(T, \chi)=\min _{u \in T}|\chi(u)|-1$. The treewidth of $G$ is the smallest width in any tree decomposition of $G$.

## 3 Counting designs for multiple structures is \#P-hard

Now we turn to the complexity of \#Designs $(G)$, the problem of computing the number of valid sequences for a given compatibility graph $G=(V, E)$. Note that this problem corresponds to the
partition function problem in a simple $(0 / \infty)$-valued base pair models, with $\beta \neq 1$. As previously noted [14], a set of target structures admits a valid design iff its compatibility graph is bipartite, which can be tested in linear time. Moreover, without $\{\mathrm{G}, \mathrm{U}\}$ base pairs, any connected component $C \in \mathrm{CC}(G)$ is entirely determined by the assignment of a single of its nucleotides. The number of valid designs is thus simply $4^{\# \mathrm{CC}(G)}$, where $\# \mathrm{CC}(G)$ is the number of connected components.

The introduction of $\{G, U\}$ base pairs radically changes this picture, and we show that valid designs for a set of structures cannot be counted in polynomial time, unless \#P = FP. The latter equality would, in particular, imply the classic $\mathrm{P}=\mathrm{NP}$, and solving \#Designs $(G)$ is polynomial time is therefore probably difficult.

To establish that claim, we consider instances $G=\left(V_{1} \cup V_{2}, E\right)$ that are strongly connected and bipartite $\left(\left(V_{1} \times V_{2}\right) \cap E=\varnothing\right)$, noting that hardness over restricted instances implies hardness of the general problem. Moreover remark that, as observed in Subsec. 4.2, assigning a nucleotide to a position $u \in V$ constrains the parity ( $\{\mathrm{A}, \mathrm{G}\}$ or $\{\mathrm{C}, \mathrm{U}\}$ ) of all positions in the connected component of $u$. For this reason, we restrict our attention to the counting of valid designs up to trivial ( $\mathrm{A} \leftrightarrow \mathrm{C} / \mathrm{G} \leftrightarrow \mathrm{U}$ ) symmetry, by constraining the positions in $V_{1}$ (resp. $V_{2}$ ) to only A and G (resp. C and U). Let Designs ${ }^{\star}(G)$ denote the subset of all designs for $G$ under this constraint, noting that \#Designs $(G)=2 \cdot \mid$ Designs $^{\star}(G) \mid$.

We remind that an independent set of $G=(V, E)$ is a subset $V^{\prime} \subseteq V$ of nodes that are not connected by any edge in $E$. Let $\operatorname{IndSets}(G)$ denote the set of all independent sets in $G$. Now, consider the function $\Psi: \operatorname{Designs}^{\star}(G) \rightarrow \operatorname{IndSets}(G)$ defined by $\Psi(f):=\{v \in V \mid f(v) \in\{\mathrm{A}, \mathrm{C}\}\}$.

Proposition 1. $\Psi$ is a bijection between Designs ${ }^{\star}(G)$ and $\operatorname{IndSets}(G)$.
Proof. Let us establish the injectivity of $\Psi$, i.e. that $\Psi(f) \neq \Psi\left(f^{\prime}\right)$ for all $f \neq f^{\prime}$. If $f \neq f^{\prime}$, then there exists a node $v \in V$ such that $f(v) \neq f^{\prime}(v)$. Assume that $v \in V_{1}$, and remind that the only nucleotides allowed in $V_{1}$ are A and G. Since $f(v) \neq f^{\prime}(v)$, then we have $\left\{f(v), f^{\prime}(v)\right\}=\{\mathrm{A}, \mathrm{G}\}$ and we conclude that $\Psi(f)$ differs from $\Psi\left(f^{\prime}\right)$ at least with respect to its inclusion/exclusion of $v$.

We turn to the surjectivity of $\Psi$, i.e. the existence of a preimage for each element $S \in \operatorname{IndSets}(G)$. Let us consider the function $f$ defined as

$$
\forall v_{1} \in V_{1}, f\left(v_{1}\right)=\left\{\begin{array}{ll}
\mathrm{A} & \text { if } v_{1} \in S  \tag{2}\\
\mathrm{G} & \text { if } v_{1} \notin S
\end{array} \quad \forall v_{2} \in V_{2}, f\left(v_{2}\right)= \begin{cases}\mathrm{C} & \text { if } v_{2} \in S \\
\mathrm{U} & \text { if } v_{2} \notin S\end{cases}\right.
$$

One easily verifies that $\Psi(f)=S$.
We are then left to determine if $f$ is a valid design for $G$, i.e. if for each $\left(v, v^{\prime}\right) \in E$ one has $\left\{f(v), f\left(v^{\prime}\right)\right\} \in \mathcal{B}$. Since $G$ is bipartite, any edge in $E$ involves two nodes $v_{1} \in V_{1}$ and $v_{2} \in V_{2}$. Remark that, among all the possible assignments $f\left(v_{1}\right)$ and $f\left(v_{2}\right)$, the only invalid combination of nucleotides is $\left(f\left(v_{1}\right), f\left(v_{2}\right)\right)=(\mathrm{A}, \mathrm{C})$. However, such nucleotides are assigned to positions that are in the independent set $S$, and therefore cannot be adjacent. We conclude that $\Psi$ is surjective, and thus bijective.

Now we can build on the connection between the two problems to obtain complexity results for \#Designs. Counting independent sets in bipartite graphs (\#BIS) is indeed a well-studied \#P-hard problem [15], from which we immediately conclude:

Corollary 1. \#Designs is \#P-hard
Proof. Note that \#BIS is also \#P-hard on connected graphs, as the number of independent sets for a disconnected graph $G$ is given by $|\operatorname{IndSets}(G)|=\prod_{c c \in C C(G)}|\operatorname{IndSets}(c c)|$. Thus any efficient algorithm for \#BIS on connected instances provides an efficient algorithm for general graphs.

Let us now hypothesize the existence of a polynomial-time algorithm $\mathcal{A}$ for \#Designs over strongly-connected graphs $G$. Now consider the polynomial-time algorithm $\mathcal{A}^{\prime}$ that first executes $\mathcal{A}$ on $G$ to produce \#Designs $(G)$, and returns \#Designs $(G) / 2=\left|\operatorname{Designs}{ }^{\star}(G)\right|=|\operatorname{IndSets}(G)|$. We conclude that $\mathcal{A}^{\prime}$ solves \#BIS in polynomial-time. This means that \#Designs is at least as hard as \#BIS, thus does not admit a polynomial time exact algorithm unless \#P = FP.

## 4 An FPT algorithm for sampling Boltzmann-weighted designs

For our algorithmic description, we translate the concepts of Section 2 to the formalism of constraint networks, here specialized as RNA design network. This allows us to base our algorithm on cluster tree elimination (CTE) by Rina Dechter [8]. In the RNA design network, sequences $S \in \mathcal{S}_{n}$ are isomorphically modeled as assignments $a_{S}$ of bases to $n$ variables, each associated to a sequence position. The functions $f \in \mathcal{F}$ of Section 2, are interpreted as functions on the network's variables.

Definition 2 (RNA design network). An RNA design network is a tuple $\mathcal{N}=(\mathcal{X}, \mathcal{F})$ such that:
$-\mathcal{X}$ is a set of variables $\left\{x_{1}, \ldots, x_{n}\right\}$ associated with the sequence positions
$-\mathcal{F}$ is a set of functions $f: \mathcal{S}_{n} \rightarrow \mathbb{R}$, each function $f \in \mathcal{F}$ being associated with the set $\operatorname{vars}(f)=$ $\left\{x_{i} \mid i \in \operatorname{dep}(f)\right\} \subset X$ of variables.

A (partial) assignment is a function $a: \mathcal{X}^{\prime} \rightarrow \Sigma$ that maps the variables $\mathcal{X}^{\prime} \subseteq \mathcal{X}$ to bases; we call $\mathcal{X}^{\prime}$ the domain of the assignment $a$, written $\operatorname{dom}(a) ; a$ is total iff $\operatorname{dom}(a)=\mathcal{X}$. For assignments $a$ and functions $f$, we define the special notation $f[a]$ to evaluate $f$ for $a$; i.e. $f[a]:=f(S)$, for any sequence $S$ where $S_{i}=a(i)$ for all $i \in \operatorname{dep}(f)$. Then, the energy $\operatorname{e}_{\mathcal{N}}(S)$ of a sequence $S$ in a network $\mathcal{N}$ is defined as sum of the values of all functions in $f \in \mathcal{F}$ evaluated for $a_{S}$, i.e. $\mathrm{e}_{\mathcal{N}}(S):=\sum_{f \in F} f\left[a_{S}\right]$.

The network energy $\mathrm{e}_{\mathcal{N}}(S)$ corresponds to the energy in Eq. (1), where this energy is modeled as sum of the functions in $\mathcal{F}$. Consequently, $\mathcal{Z}_{\mathcal{R}}$ of Eq. (1) is modeled as network partition function $\mathcal{Z}_{\mathcal{N}}:=\sum_{S} \exp \left(-\beta \mathrm{e}_{\mathcal{N}}(S)\right)=\sum_{S} \prod_{f \in F} \exp \left(-\beta \cdot f\left[a_{S}\right]\right)$.

### 4.1 Partition function and Boltzmann sampling through stochastic backtrack

The minimum energy, counting, and partition function over RNA design network can be computed by dynamic programming based on a tree decomposition of the network's dependency graph (i.e. cluster tree elimination). We focus on the efficient computation of the partition function.

Let us now introduce some definitions. A cluster tree for the network $\mathcal{N}=(\mathcal{X}, \mathcal{F})$ is a tuple $(T, \chi, \phi)$, where $(T, \chi)$ is a tree decomposition of $G_{\mathcal{F}}$, and $\phi(v)$ represents a set of functions $f$, each uniquely assigned to a node $v \in T ; \operatorname{vars}(f) \subseteq \chi(v)$ and $\phi(v) \cap \phi\left(v^{\prime}\right)=\varnothing$ for all $v \neq v^{\prime}$. For two nodes $v$ and $u$ of the cluster tree, define their separator as $\operatorname{sep}(u, v):=\chi(u) \cap \chi(v)$; moreover, we define the difference variables from $u$ to $v$ by $\operatorname{diff}(u \rightarrow v):=\chi(v)-\operatorname{sep}(u, v)$.

Denote by $\mathcal{A}(\mathcal{Y})$ the set of all assignments of the variables in $\mathcal{Y}$; moreover, given non-overlapping assignments $a^{\prime}$ and $a^{\prime \prime}$, we write $a^{\prime} \mid a^{\prime \prime}$ to denote the assignment defined as $a^{\prime}$ and $a^{\prime \prime}$ respectively on $\operatorname{dom}\left(a^{\prime}\right)$ and $\operatorname{dom}\left(a^{\prime \prime}\right)$. Finally we assume, w.l.o.g., that all variable difference sets $\operatorname{diff}(u \rightarrow v)$ are restricted to a single variable: for any given cluster tree, an equivalent (in term of treewidth) cluster tree can always be obtained by inserting at most $\Theta(|\mathcal{X}|)$ additional clusters.

Let us now consider the computation of the partition function. Given is the RNA design network $\mathcal{N}=(\mathcal{X}, \mathcal{F})$ and its cluster tree decomposition $(T, \chi, \phi)$. W.l.o.g, we assume that $T$ is connected and contains a dedicated node $r$, with $\chi(r)=\varnothing$ and $\phi(r)=\varnothing$, added as a virtual root $r$ connected

```

        for \(a^{\prime} \in \mathcal{A}(\operatorname{diff}(u \rightarrow v))\) do
            \(p \leftarrow \operatorname{product}\left(\exp \left(-\beta f\left[a \mid a^{\prime}\right]\right)\right.\) for \(\left.f \in \phi(u)\right)\);
            \(p \leftarrow p \times \operatorname{product}\left(m_{w \rightarrow u}\left[a \mid a^{\prime}\right]\right.\) for \(\left.(w \rightarrow u) \in T\right)\);
            \(m_{u \rightarrow v}[a] \leftarrow m_{u \rightarrow v}[a]+p ;\)
    return \(m\);
```

Algorithm 1: FPT computation of the partition function using dynamic programming (CTE).
to a node in each connected component of $T$. Now, we consider the set of directed edges $E_{T}^{r}$ of $T$ oriented to $r$; define $T_{r}(u)$ as the induced subtree of $u$. Algorithm 1 computes the partition function by passing messages along these directed edges $u \rightarrow v$ (i.e. always from some child $u$ to its parent $v$ ). Each message is a function on variables vars $(m) \subseteq \mathcal{X}$ to $\mathbb{R} \cup\{\infty\}$. The message from $u$ to $v$ represents the partition functions of the subtree of $u$ for all possible assignments to the variables $\operatorname{vars}(m)=\operatorname{sep}(u, v)$. Its correctness can be shown by induction over $T$ (Appendix D ). After running Alg. 1, multiplying the 0 -ary messages sent to the root $r$ yields the total partition function: $\mathcal{Z}_{\mathcal{N}}=\prod_{(u \rightarrow r) \in T} m_{u \rightarrow r}[\varnothing]$.

The partition functions can then direct a stochastic backtrack to achieve Boltzmann sampling of sequences, such that one samples from the Boltzmann distribution of a given desgin network $\mathcal{N}$. The sampling algorithm assumes that the cluster tree was expanded and the messages $m_{u \rightarrow v}$ for the edges in $E_{T}^{r}$ are already generated by Algorithm 1 for the expanded cluster tree. Algorithm 2 defines the recursive procedure $\operatorname{Sample}(u, a)$, which returns an assignment of all variables in the subtree rooted at $u$ from the Boltzmann-distribution. Called on $r$ and the empty assignment, the procedure returns a total assignment corresponding to a Boltzmann-distributed random sequence.

### 4.2 Computational complexity of the multiple target sampling algorithm

First, we observed that the computation time of tree decomposition (GreedyFillIn, implemented in LibTW [29]) for multi-target sampling is negligible compared to Alg. 1 (Appendix B and C); consequently, we discuss complexities without the tree decomposition step.

For our analysis, we define the maximum separator size $s$ as $\max _{u, v \in V}|\operatorname{sep}(u, v)|$ and denote the maximum size of $\operatorname{diff}(u \rightarrow v)$ over $(u, v) \in E_{T}^{r}$ as $D$. Generally, without specific optimizations, running Alg. 1 requires $\mathcal{O}\left((|\mathcal{F}|+|V|) \cdot 4^{w+1}\right)$ and $\mathcal{O}\left(|V| \cdot 4^{s}\right)$ space (Appendix E); Alg. 2 would require $\mathcal{O}\left((|\mathcal{F}|+|V|) \cdot 4^{D}\right)$ per sample on arbitrary tree decompositions (Appendix E). W.l.o.g. we assume that $D=1$; note that tree decompositions can generally be transformed, such that $\operatorname{diff}(u \rightarrow v) \leq 1$. Moreover, the size of $\mathcal{F}$ is linearly bounded: for $k$ input structures for sequences of length $n$, the energy function is expressed by $\mathcal{O}(n k)$ functions. Finally, the number of cluster tree nodes is in $O(n)$, such that $|\mathcal{F}|+|V| \in \mathcal{O}(n k)$.

As already noted by Flamm et al [14], the requirement of canonical base pairing induces a bi-partition of each connected component of the compatibility graph, such that the variables of one partition are restricted to values $\{A, G\}$, but for other partition, to values $\{C, U\}$. This suggests a strong optimization of our algorithms, which reduces the basis in the exponential factor from 4 to 2. The price for this reduction is a binary choice for each of $c$ connected component. For each of the $2^{c}$ combinations, the partition functions can be computed separately in $O\left(n m 2^{w+1}\right)$ time. This

```

            for \((v \rightarrow w) \in T\) do
                \(a_{\text {res }} \leftarrow a_{\text {res }} \mid \operatorname{Sample}\left(v, a \mid a^{\prime} ; T, \chi, \phi, m\right) ;\)
            return \(a_{\text {res }}\);
```

Algorithm 2: Stochastic backtrack algorithm for assignments in the Boltzmann distribution.
strategy is applied only if $c<w+1$. Finally, we compute the sums of the partition functions for all possible combinations.

Theorem 1 (Partition function and sampling complexity). For sequence length $n$, $k$ target structures, treewidth $w$ and a compatibility graph having c connected components, $t$ sequences are sampled from the Boltzmann distribution in $\mathcal{O}\left(2^{d} n k+t n k\right)$ time, where $d:=\min (w+c+1,2(w+1))$.

### 4.3 Encoding sequence features, constraints, and energy models.

The functions in $\mathcal{F}$ allow expressing complex features of the sequences alone, e.g. rewarding or penalizing specific sequence motifs, as well as features depending on the target structures. Naturally, hard constraints, which enforce or forbid features, can also be expressed by functions that assign infinite penalties to invalid partial assignments. More concretely, we briefly discuss the modeling of RNA energy models in our framework.

In simple base pair-based energy models, energy is defined as the sum of base pair (pseudo)energies. If base pair energies $E_{k}^{\mathrm{bp}}(i, j, x, y)$ (where $i$ and $j$ are sequence positions, $x$ and $y$ are bases in $\Sigma$ ) are given for each target structure $\ell$, s.t. $E\left(S ; R_{\ell}\right):=\sum_{(i, j) \in R_{\ell}} E_{k}^{\mathrm{bp}}\left(i, j, S_{i}, S_{j}\right)$, we encode the network energy by the set of functions $f$ for each base pair $(i, j) \in R_{\ell}$ of each input structure $R_{\ell}$ that evaluate to $w_{\ell} E_{k}^{\mathrm{bp}}\left(i, j, a\left(x_{i}\right), a\left(x_{j}\right)\right)$ under assignment $a$.

More complex Loop-based energy models - e.g. the Turner model, which among others adds energy terms for special loops and dangling ends-are encoded as straightforward extensions. An interesting stripped-down variant of the nearest neighbor model is the stacking energy model. This model assigns non-zero energy contributions only to stacks, i.e. interior loops with closing base pair $(i, j)$ and inner base pair $(i+1, j-1)$.

The arity of the introduced functions provides an important bound on the treewidth of the network (and therefore computational complexity). Thus, it is noteworthy that the base pair energy model requires only binary functions; the stacking model, only quarternary dependencies. This arity is increased in a few cases by the commonly used Turner 2004 model [28] for encoding tabulated special hairpin and interior loop contributions, which depend on up to nine bases for the interior loops with a total of 5 unpaired bases (" 2 x 3 " interior loops) -all other energy contributions (like dangling ends) still depend on at most four bases of the sequence.

### 4.4 Extension to multidimensional Boltzmann sampling

The flexibility of our framework supports an advanced sampling technique, named multidimensional Boltzmann sampling [3] to (probabilistically) enforce additional constraints. This technique was previously used to control the GC-content [31,25] and dinucleotide content [33] of sampled RNA sequences; it enables explicit control of the free energies $\left(E_{1}^{\star}, \ldots, E_{k}^{\star}\right)$ of the single targets.

Multidimensional Boltzmann sampling requires the ability to sample from a weighted distribution over the set of compatible sequences, where the probability of a sequence $S$ with free energies $\left(E_{1}, \ldots, E_{k}\right)$ for its target structures is $\mathbb{P}(S \mid \boldsymbol{\pi})=\frac{\prod_{k=1}^{k} \pi_{i}^{-E_{i}}}{\mathcal{Z}_{\boldsymbol{\pi}}}$, where $\boldsymbol{\pi}:=\left(\pi_{1} \cdots \pi_{k}\right)$ is a vector of positive real-valued weights, and $\mathcal{Z}_{\boldsymbol{\pi}}$ is the weighted partition function. Such a distribution can be induced by a simple modification of the functions described in Sec. 4.3, where any energy function $E(a)$ for a structure $\ell$ is replaced by $E^{\prime}(a):=\log \left(\pi_{\ell}\right) E(a) / \beta$. The probability of a sequence $S$ is thus proportional to $\prod_{\ell=1}^{k} e^{-\log \left(\pi_{\ell}\right) E_{i}}=\prod_{\ell=1}^{k} \pi_{i}^{-E_{i}}$.

One then needs to learn a weights vector $\boldsymbol{\pi}$ such that, on average, the targeted energies are achieved by a random sequences in the weighted distribution, i.e. such that $\mathbb{E}\left(E_{\ell}(S) \mid \boldsymbol{\pi}\right)=E_{\ell}^{\star}$, $\forall \ell \in[1, k]$. The expected value of $E_{\ell}$ is always decreasing for increasing weights $\pi_{\ell}$ (see App. G). More generally, computing a suitable $\boldsymbol{\pi}$ can be restated as a convex optimization problem, and be efficiently solved using a wide array of methods [9,2]. In practice, we use a simple heuristics which starts from an initial weight vector $\pi^{[0]}:=(\exp (\beta), \ldots, \exp (\beta))$ and, at each iteration, generates a sample $\mathcal{S}$ of sequences. The expected value of an energy $E_{\ell}$ is estimated as $\hat{\mu}_{\ell}(\mathcal{S})=\sum_{S \in \mathcal{S}} E_{\ell}(S) /|\mathcal{S}|$, and the weights are updated at the $t$-th iteration by $\pi_{\ell}^{[t+1]}=\pi_{\ell}^{[t]} \cdot \gamma^{\hat{\mu}_{\ell}(\mathcal{S})-E_{\ell}^{\ell}}$. While heuristic in nature, this basic iteration was elected in our initial version of RNARedPrint because of its reasonable empirical behavior.

A further rejection step is applied to the generated structures to retain only sequences whose energy for each structure $R_{\ell}$ belongs to $\left[E_{\ell}^{\star} \cdot(1-\varepsilon), E_{\ell}^{\star} \cdot(1+\varepsilon)\right]$, for $\varepsilon \geq 0$ some predefined tolerance. The rationale for a rejection approach follows from: i) Enacting an exact control over the energies would be technically hard and costly. Indeed, controlling the energies through dynamic programming would require explicit convolution products, generalizing Cupal et al [7], inducing additional $\Theta\left(n^{2 k}\right)$ time and $\Theta\left(n^{k}\right)$ space overheads; ii) Induced distributions are typically concentrated. Intuitively, unless sequences are fully constrained individual energy terms are independent enough so that their sum is concentrated around its mean - the targeted energy (cf Fig. 2). For base pair-based energy models and special compatibility graph (paths, cycles...) this property rigorously follows from analytic combinatorics, see Bender-Richmond-Williamson [1] and Drmota [12]. In such cases, the expected number of rejections before reaching the targeted energies grows like $\Theta(1)$ when $\varepsilon \geq 1 / \sqrt{n}$, and $\Theta\left(n^{k / 2}\right)$ when $\varepsilon=0$. The GC-content of designs can also be controlled, jointly and in a similar way, as done in IncaRNAtion [25].

## 5 Results

### 5.1 Implementation targeting Turner energies and GC-content

We implemented the Boltzmann sampling approach (Algorithms 1 and 2), performing sampling for given target structures and weights $\pi_{1}, \ldots, \pi_{n}$; moreover on top, multi-dimensional Boltzmann sampling (see Section 4.4) to target specific energies and GC-content. Our tool RNARedPrint evaluates energies according to the base pair energy model or the stacking energy model, using parameters which were trained to approximate Turner energies (Appendix F).

Fig. 2: Targeting specific energies using multi-dimensional Boltzmann sampling. (A) Turner energy distributions for three target structures (right) while targeting $(-40,-40,-20)$ and $(-20,-20,-20)$ free energy vectors. For comparison, we show the distribution of uniform and Boltzmann samples; respectively associated with homogenous weights 1 and $e^{\beta}$. (B) Accuracy of targeting over all target structures of the Modena benchmark instances RNAtabupath, 3str and 4str. Shown is the relative deviation of targeted and achieved energies in the simple stacking model and the Turner model.

To capture the realistic Turner model $E_{\mathcal{T}}$, we exploit its very good correlation (supp. Fig 6) with our simple stacking-based model $E_{\mathcal{S}}$. Namely, we observe a structure-specific affine dependency between these Turner and stacking energy models, so that $E_{\mathcal{T}}\left(S_{\ell} ; R_{\ell}\right) \approx \gamma_{\ell} E_{\mathcal{S} ; R_{\ell}}\left(S_{\ell}\right)+\delta_{\ell}$ for each structure $R_{\ell}$. We learn the ( $\gamma_{\ell}, \delta_{\ell}$ ) parameters from a set of sequences generated with homogenous weights $w=e^{\beta}$, tuning only the GC-content to a predetermined target frequency. Finally, we adjust the targeted energy of our stacking model to $E_{\mathcal{S}}^{\star}=\left(E_{\mathcal{T}}^{\star}-\delta_{\ell}\right) / \gamma_{\ell}$.

To illustrate our above strategy, we sampled $n=1000$ sequences targeting $\mathrm{GC}_{\text {target }}=0.5$ and different Turner energies for the three structure targets of an example instance. Figure 2A illustrates how the Turner energy distributions of the shown target structures can be accurately shifted to prescribed target energies; for comparison, we plot the respective energy distribution of uniformly and Boltzmann sampled sequences. Figure 2B summarizes the targeting accuracy for the single structure energies over a larger set of instances from the Modena benchmark. We emphasize that only the simple stacking energies are directly targeted (at $\pm 10 \%$ tolerance, expect for a few hard instances). Due to our linear adjustment, we still achieve well controlled energies in the ultimately relevant Turner energy model.

### 5.2 Generating high-quality seeds for further optimization

We empirically study the capacity of RNARedPrint to improve the generation of seed sequences for subsequent local optimizations, showing an important application in biologically relevant scenario.

For a multi-target design instance, individual reasonable target energies are estimated from averaging the energy over samples at relatively high weights $e^{\beta}$, controlling the GC-content at $50 \%$. For each instance of the Modena benchmark [27], we estimated such target energies and subsequently generated 1000 seed sequences at these energies. As its rationale, this procedure is tailored to produce sequences with similar Turner energy that favor the stability of the target structures having moderate GC-content; all these properties are desirable objectives for RNA design. All sampled sequences are evaluated under the multi-stable design objective function of [17]:

$$
\begin{equation*}
f(S)=\frac{1}{k} \sum_{\ell}^{k}\left(E\left(S, R_{\ell}\right)-G(S)\right)+\xi \frac{2}{k(k-1)} \sum_{\ell<j}^{k}\left|E\left(S, R_{\ell}\right)-E\left(S, R_{j}\right)\right| \tag{3}
\end{equation*}
$$

|  | Dataset | RNARedPrint | Uniform | Improvement |
| :--- | :--- | :---: | :---: | :---: |
| Seeds | RNAtabupath | $21.67( \pm 4.38)$ | $37.74( \pm 6.45)$ | $73 \%$ |
|  | 3str | $18.09( \pm 3.98)$ | $30.49( \pm 5.41)$ | $71 \%$ |
|  | 4str | $19.94( \pm 3.84)$ | $32.29( \pm 5.24)$ | $63 \%$ |
| Optimized | RNAtabupath | $5.84( \pm 1.31)$ | $7.95( \pm 1.76)$ | $28 \%$ |
|  | 3str | $5.08( \pm 1.10)$ | $7.04( \pm 1.52)$ | $31 \%$ |
|  | 4str | $8.77( \pm 1.48)$ | $13.13( \pm 2.13)$ | $37 \%$ |

Table 1: Comparison of the multi-stable design objective function (Eq. (3) of sequences sampled by RNARedPrint vs. uniform samples for three benchmark sets; before (seeds) and after optimization (optimized). We report the average scores with standard deviations. Smaller scores are better; the final column reports our improvements over uniform sampling.

Using our strategy, we generated at least 1000 seeds per instance of the subsets RNAtabupath, 3 str, and 4 str, of the Modena benchmark set with 2,3, and 4 structures. The results are compared, in terms of their value for the objective function of Eq. (3), to seed sequences uniformly sampled using RNAblueprint [17] (Table 1, seeds). Our first analysis reveals that Boltzmann-weighted sequences constitute better seeds, associated with better values ( $\sim 69 \%$ improvement on average), compared to uniform seeds for all instances of our benchmark (Supp. section H).

Moreover, for each generated seed sequence, we optimized the objective function (3) through an adaptive greedy walk consisting of 500 steps. At each step, we resampled (uniformly at random) the positions of a randomly selected component in the compatibility graph, and accepted the modification only if it resulted in a gain, as described in RNAblueprint [17]. Once again, for all instances, we observe a positive improvement of the quality of Boltzmann designs over uniform ones, suggesting a superior potential for optimization ( $\sim 32 \%$ avg improvement, Table 1, optimized). This improvement is however more modest than in the absence of optimization, but we attribute this relative decay to the uniform nature of the resampling strategy, which somehow ends up canceling the benefits of the initial Boltzmann distribution, by uniformizing the sequence over longer runs. This suggests an alternative resampling strategy based on Boltzmann-distributed steps.

## 6 Conclusion

Motivated by the - here established-hardness of the problem, we introduced a general framework and efficient algorithms for design of RNA sequences to multiple target structures with fine-tuned properties. Our method combines an FPT stochastic sampling algorithm with multi-dimensional Boltzmann sampling over distributions controlled by expressive RNA energy models. Compared to the previously best available sampling method (uniform sampling), this approach generated significantly better seed sequences for instances of a common multi-target design benchmark.

The presented method enables new possibilities for sequence generation in the field of RNA sequence design by enforcing additional constraints, like the GC-content, while controlling the energy of multiple target structures. Thus it presents a major advance over previously used ad-hoc sampling and even uniform sampling strategies. We have shown the practicality of such controlled sequence generation and studied its use for multi-target RNA design. Moreover, our framework is already equipped to include more complex sequence constraints, including mandatory/forbidden motifs at specific positions or anywhere in the designed sequences. It could also support negative design principles, for instance by penalizing a set of alternative helices/structures. However, such extensions require delicate calibration, and will be the object of future work.

## Fixed-Parameter Tractable Sampling for RNA Design with Multiple Target Structures

## A Approximate counting and random generation

In fact, not only is \#BIS a reference problem in counting complexity, but it is also a landmark problem with respect to the complexity of approximate counting problems. In this context, it is the representative for a class of \#BIS-hard problems [4] that are easier to approximate than \#SAT, yet are widely believed not to admit any Fully Polynomial-time Randomized Approximation Scheme. Recent results reveal a surprising dichotomy in the behavior of \#BIS: it admits a Fully Polynomial-Time Approximation Scheme (FPTAS) for graphs of max degree $\leq 5$ [32], but is as hard to approximate as the general \#BIS problem on graphs of degree $\geq 6[6]$. In other words, there is a clear threshold, in term of the max degree, separating (relatively) easy instances from really hard ones.

Additionally, let us note that, from the classic Vizing Theorem, any bipartite graph $G$ having maximum degree $\Delta$ can be decomposed in polynomial time in exactly $\Delta$ matchings. Any such matching can be reinterpreted as a secondary structure, possibly with crossing interactions (pseudoknots). These results have two immediate consequences for the pseudoknotted version of the multiple design counting problem.

Corollary 2 (as follows from [32]). The number of designs compatible with $m \leq 5$ pseudoknotted RNA structures can be approximated within any fixed ratio by a deterministic polynomial-time algorithm.

Corollary 3 (as follows from [6]). As soon as the number of pseudoknotted RNA structures strictly exceeds 5, \#Designs is as hard to approximate as \#BIS.

It is worth noting that the \#P hardness of \#Designs does not immediately imply the hardness of generating a valid design uniformly at random, as demonstrated constructively by Jerrum, Valiant and Vazirani [20]. However, in the same work, the authors establish a strong connection between the complexity of approximate counting and the uniform random generation. Namely, they showed that, for problems associated with self-reducible relations, approximate counting is equally as hard as (almost) uniform random generation. We conjecture that the (almost) uniform sampling of sequences from multiple structures with pseudoknots is in fact \#BIS-hard as soon as the number of input structures strictly exceeds 5 , as indicated by Goldberg et al. [16], motivating even further our parameterized approach.

## B Tree decomposition for RNA design instances in practice

For studying the typically expected treewidths and tree decomposition run times in multi-target design instances, we consider five sets of multi-target RNA design instances of different complexity. Our first set consists of the Modena benchmark instances.

In addition, we generated four sets of instances of increasing complexity. The instances of the sets RF3, RF4, RF5, and RF6, each respectively specify $3,4,5$, and 6 target structures for sequence
length 100. For each instance ( 100 instances per set), we generated a set of $k(k=3, \ldots, 6$ ) compatible structures as follows

- generate a random sequence of length 100
- compute its minimum free energy structure (ViennaRNA package)
- add the new structure to the instances if the resulting compatibility graph is bipartite
- repeat until $k$ structures are collected

For each instance, we generated the dependency graphs in the base pair model and in the stacking model. Then, we performed tree decomposition (using strategy "GreedyFillIn" of LibTW [29]) on each dependency graph. The obtained treewidths are reported in Fig. 3, while Fig. 4 shows the corresponding run-times of the tree decomposition. Figure 5 shows the tree decompositions for an example instance from set RF3.

Fig. 3: Treewidths for multi-target RNA design instances of different complexity. Distributions of treewidths shown as boxplots for the base pair (left) and stacking model (right).

## C Expressing higher arity functions as cliques in the dependency graph

Our implementation relies on external tools for the tree decomposition. Therefore it is not trivial that the weight functions (i.e. terms of the energy function) can be captured within the tree decompositions returned by a specific tool. In other words, it is not immediately clear how one can construct a cluster tree from an arbitrary tree decomposition for a given network.

Fortunately, we can show that, as long as the network the arguments $\operatorname{vars}(f)$ of a function $f$ are materialized by a clique within the network $\mathcal{N}$, then there exists at least one node in the tree decomposition that contains $\operatorname{vars}(f)$, thus allowing the evaluation of $f$.

Lemma 1. Let $G=(V, E)$ be an undirected graph, and $T, \chi$ be a tree decomposition for $G$. For each clique $C \subset V$, there exists a node $n \in T$ such that $C \subset \chi(v)$.

Proof. For the sake of simplicity, let us consider $T$ as rooted on an arbitrary node, inducing an orientation, and denote by $\operatorname{tvars}(n) \in V$ the set of vertices found in a node $n$ or its descendants, namely

$$
\operatorname{tvars}(n)=\chi(n) \bigcup_{n^{\prime} \in \operatorname{Children}(n)} \operatorname{tvars}\left(n^{\prime}\right)
$$

Fig. 4: Computation time of tree decompositions for multi-target RNA design instances of different complexity. Distributions of times (in ms/instance) shown as boxplots for the base pair (left) and stacking model (right).

Now consider (one of) the deepest node(s) $n \in T$, such that $C \subset \operatorname{tvars}(v)$. We are going to prove that $C \subset \chi(n)$, using contradiction, by showing that $C \not \subset \chi(n)$ implies that $T$ is not a tree decomposition.

Indeed, let us assume that $C \not \subset \chi(n)$, then there exists a node $v^{\prime} \notin \chi(n)$ whose presence in tvars $(n)$ stems from its presence in some descendant of $n$. Let us denote by $n^{\prime} \neq n$ the closest descendant of $n$ such that $v^{\prime} \in \chi\left(n^{\prime}\right)$. Now, consider a node $v \in C$ such that $v \in \operatorname{tvars}\left(v^{\prime}\right)$ and $v \notin \operatorname{tvars}\left(v^{\prime}\right)$. Such a node always exists, otherwise $n^{\prime}$, and not $n$, would be the deepest node such that $C \subset \operatorname{tvars}\left(v^{\prime}\right)$. From the definition of the tree decomposition, we know that neither $n^{\prime}$ nor its descendants may contain $v$. On the other hand, none of the parents or siblings of $n^{\prime}$ may contain $v^{\prime}$. It follows that is no node $n^{\prime \prime} \in T$ whose vertex set $\chi\left(v^{\prime \prime}\right)$ includes, at the same time, $v$ and $v^{\prime}$. Since both $v$ and $v^{\prime}$ belong to a clique, one has $\left\{v, v^{\prime}\right\} \in E$. The absence of a node in $T$ capturing an edge in $E$ contradicts our initial assumption that $T$ is tree decomposition for $G$.

We conclude that $n$ is such that $C \not \subset \chi(n)$.
This result implies that classic tree decomposition algorithms and, more importantly, implementations can be directly re-used to produce decompositions that capture energy models of arbitrary complexity, functions of arbitrary arity. Indeed, it suffices to add a clique, involving the parameters of the function, and Lemma 1 guarantees that the tree decomposition will feature one node to which the function can be associated.

## D Correctness of the FPT partition function algorithm

Theorem 2 (Correctness of Alg. 1). As computed by Alg. 1 for cluster tree ( $T, \chi, \phi$ ), the messages $m_{u \rightarrow v}$, for all edges $u \rightarrow v \in T$, yield the partition functions of subtree of $u$ for the partial assignments $a \in \mathcal{A}(\operatorname{sep}(u, v))$, i.e. the messages satisfy

$$
\begin{equation*}
m_{u \rightarrow v}[a]=\sum_{a^{\prime} \in \mathcal{A}\left(\chi\left(T_{r}(u)\right)-\operatorname{sep}(u, v)\right)} \prod_{f \in \phi\left(T_{r}(u)\right)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right), \tag{4}
\end{equation*}
$$

where $\chi\left(T_{r}(u)\right)$ denotes all $\chi$-assigned variables of nodes in $T_{r}(u)$; respectively $\phi\left(T_{r}(u)\right)$; all $\phi$ assigned functions.

Fig. 5: Example instance from RF3 (top) with its tree decompositions in the base pair (left) and stacking model (right). The respective treewidths are 2 and 12.

Proof. Note that in more concise notation, Alg. 1 computes messages such that

$$
\begin{equation*}
m_{u \rightarrow v}[a]:=\sum_{a^{\prime} \in \mathcal{A}(\operatorname{diff}(u \rightarrow v))} \prod_{f \in \phi(u)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right) \prod_{(w \rightarrow u) \in T} m_{w \rightarrow u}\left[a^{\prime} \mid a\right] . \tag{5}
\end{equation*}
$$

Proof by induction on $T$. If $u$ is a leaf, $\chi(r)=\chi\left(T_{r}(u)\right)$, there are no messages sent to $u$, and $\phi(u)=\phi\left(T_{r}(u)\right)$; implying Eq. (4). Otherwise, since the algorithm traverses edges in postorder, $u$ received from its children $w_{1}, \ldots, w_{q}$ the messages $m_{w_{1} \rightarrow u}, \ldots, m_{w_{q} \rightarrow u}$, which satisfy Eq. (4) (induction hypothesis). Let $a \in \mathcal{A}(\operatorname{sep}(u, v))$; then, $m_{u \rightarrow v}[a]$ is computed by the algorithm according
to Eq. (5). We rewrite as follows

$$
\begin{aligned}
& \sum_{a^{\prime} \in \mathcal{A}(\operatorname{diff}(u \rightarrow v))} \prod_{f \in \phi(u)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right) \prod_{(w \rightarrow u) \in T} m_{w \rightarrow u}\left[a^{\prime} \mid a\right] \\
& =\sum_{a^{\prime} \in \mathcal{A}(\chi(u)-\operatorname{sep}(u, v))} \prod_{f \in \phi(u)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right) \prod_{i=1}^{q} m_{w_{i} \rightarrow u}\left[a^{\prime} \mid a\right] \\
& =I_{I H} \sum_{a^{\prime} \in \mathcal{A}(\chi(u)-\operatorname{sep}(u, v))} \prod_{f \in \phi(u)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right) \prod_{i=1}^{q} \sum_{a^{\prime \prime} \in \mathcal{A}\left(\chi\left(T_{r}\left(w_{i}\right)\right)-\operatorname{sep}\left(w_{i}, u\right)\right)} \prod_{f \in \phi\left(T_{r}\left(w_{i}\right)\right)} \exp \left(-\beta f\left[a^{\prime \prime}\left|a^{\prime}\right| a\right]\right) \\
& ={ }_{*} \sum_{a^{\prime} \in \mathcal{A}(\chi(u)-\operatorname{sep}(u, v))} \sum_{a^{\prime \prime} \in \mathcal{A}\left(\cup_{i=1}^{q} \chi\left(T_{r}\left(w_{i}\right)\right)-\operatorname{sep}\left(w_{i}, u\right)\right)} \prod_{f \in \phi(u)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right) \prod_{f \in \phi\left(T_{r}\left(w_{i}\right)\right)} \exp \left(-\beta f\left[a^{\prime \prime}\left|a^{\prime}\right| a\right]\right) \\
& ={ }_{(* *)} \sum_{a^{\prime} \in \mathcal{A}\left(\chi\left(T_{r}(u)\right)-\operatorname{sep}(u, v)\right)} \prod_{f \in \phi\left(T_{r}(u)\right)} \exp \left(-\beta f\left[a^{\prime} \mid a\right]\right)
\end{aligned}
$$

To see $\left(^{*}\right)$ and $\left({ }^{* *}\right)$, we observe:

- The sets $\chi(u)-\operatorname{sep}(u, v)$ and $\chi\left(T_{r}\left(w_{i}\right)\right)-\operatorname{sep}\left(w_{i}, u\right)$ are all disjoint due to Def. 1, property 2 . First, this property implies that any shared variable between the subtrees of $w_{i}$ and $w_{j}$ must be in $\chi\left(w_{i}\right), \chi\left(w_{j}\right)$ and $\chi(u)$, thus the variables of $\chi\left(T_{r}\left(w_{i}\right)\right)-\operatorname{sep}\left(w_{i}, u\right)$ are disjoint. Second, if a variable $\chi\left(T_{r}\left(w_{i}\right)\right)$ occurs in $\chi(u)$, it must occur in $\chi\left(w_{i}\right)$ and consequently in $\operatorname{sep}(u, v)$.
- The union of the sets $\chi(u)-\operatorname{sep}(u, v)$ and $\chi\left(T_{r}\left(w_{i}\right)\right)-\operatorname{sep}\left(w_{i}, u\right)$ is $\left.\chi\left(T_{r}(u)\right)-\operatorname{sep}(u, v)\right)$.

## E General complexity of the partition function computation by cluster tree elimination and generation of samples

Proposition 2. Given a cluster tree $(T, \chi, \phi), T=(V, E)$ of the $R N A$ design network $\mathcal{N}=(\mathcal{X}, \mathcal{F})$ with treewidth $w$ and maximum separator size $s$, computing the partition function by Algorithm 1 takes $O\left((|F|+|V|) \cdot 4^{w+1}\right)$ time and $O\left(|V| 4^{s}\right)$ space (for storing all messages). The sampling step has time complexity of $O\left((|F|+|V|) \cdot 4^{D}\right)$ per sample.

Proof (Proposition 2). Let $d_{u}$ denote the degree of node $u$ in $T, s_{u}$ is the size of the separator between $u$ and its parent in $T$ rooted at $r$. For each node in the cluster tree, Alg. 1 computes one message by combining $\left(|\phi(u)|+d_{u}-1\right)$ functions, each time enumerating $4^{|\chi(u)|}$ combinations; Alg. 2 computes $4^{|\chi u|-s_{u}}$ partition functions each time combining $\left(|\phi(u)|+d_{u}-1\right)$ functions. $4^{|\chi(u)|}$ is bound by $4^{w+1}$ and $4^{|\chi u|-s_{u}}$ by $4^{D}$; moreover $\sum_{u \in V}\left(|\phi(u)|+d_{u}-1\right)=|F|+|V|-1$.

## F Parameters for the base pair and the stacking energy model

We trained parameters for two RNA energy models to approximate the Turner energy model, as implemented in the ViennaRNA package. In the base pair model, the total energy of a sequence $S$ for an RNA structure $R$ is given as sum of base pair energies, where we consider six types of base pairs distinguishing by the bases A-U, C-G or G-U (symmetrically) and between stacked and non-stacked base pairs; here, we consider base pairs $(i, j) \in R$ stacked iff $(i+1, j-1) \in R$, otherwise non-stacked. In the stacking model, our features are defined by the stacks, i.e. pairs $(i, j)$ and $(i+1, j-1)$ which both occur in $R$; we distinguish 18 types based on $S_{i}, S_{j}, S_{i+1}, S_{j-1}$ (i.e. all combinations that allow canonical base pairs; the configurations $S_{i}, S_{j}, S_{i+1}, S_{j-1}$ and $S_{i+1}, S_{j-1}, S_{j}, S_{i}$ are symmetric).

Both models describe the energy assigned to a pair of sequence and structure in linear dependency of the number of features and their weights. We can thus train weights for linear predictors of the Turner energy in both models.

For this purpose, we generated 5000 uniform random RNA sequences of random lengths between 100 and 200. For each sample, we predict the minimum free energy and corresponding structure using the ViennaRNA package; then, we count the distinguished features (i.e., base pair or stack types). The parameters are estimated fitting linear models without intercept ( R function lm). For both models, R reports an adjusted R -squared value of 0.99 . The resulting parameters are reported in Tables 2 and 3.

For validating the trained parameters, we generate a second independent test set of random RNA sequences in the same way. Figure 6 shows correlation plots for the trained parameters in the base pair and stacking models for predicting the Turner energies in the test set with respective correlations of 0.95 an 0.94 .

Fig. 6: Validation of the trained parameters for the A) base pair model B) stacking model for predicting energies of the independently sampled sequences in the test set. We show correlation plots against the Turner energies reported by the ViennaRNA package.

## G Monotonicity of the partial derivatives within weight calibration

In weighted distributions, one witnesses a fairly predictable impact of the variation of any weight $\pi_{\ell}$ over the expected value $\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right), \pi:=\left(\pi_{1} \cdots \pi_{k}\right)$, of the free energy $E_{\ell}$ of structure $\ell$. Let us first remind the probability of a sequence $S$ in the weighted distribution

$$
\mathcal{B}_{\boldsymbol{\pi}}(S)=\prod_{i=1}^{k} \pi_{i}^{-E_{i}(S)}, \quad \mathcal{Z}_{\boldsymbol{\pi}}=\sum_{S^{\prime}} \mathcal{B}_{\boldsymbol{\pi}}\left(S^{\prime}\right) \quad \text { and } \quad \mathbb{P}(S \mid \boldsymbol{\pi})=\frac{\mathcal{B}_{\boldsymbol{\pi}}(S)}{\mathcal{Z}_{\boldsymbol{\pi}}}
$$

Remind also the definition of the expectation of $E_{\ell}(S)$, for $S$ a Boltzmann-distributed sequence:

$$
\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right)=\sum_{S} E_{\ell}(S) \cdot \mathbb{P}(S \mid \boldsymbol{\pi}) .
$$

We first remark that the partial derivative of $\mathcal{B}$ yields

$$
\frac{\partial \mathcal{B}_{\boldsymbol{\pi}}(S)}{\partial \pi_{\ell}}=-E_{\ell}(S) \cdot \pi_{\ell}^{-E_{\ell}(S)-1} \prod_{\substack{i=1 \\ i \neq \ell}}^{k} \pi_{i}^{-E_{i}(S)}=\frac{-E_{\ell}(S)}{\pi_{\ell}} \cdot \mathcal{B}_{\boldsymbol{\pi}}(S)=-E_{\ell}(S) \cdot \mathbb{P}(S \mid \boldsymbol{\pi}) \cdot \frac{\mathcal{Z}_{\boldsymbol{\pi}}}{\pi_{\ell}}
$$

while the partial derivative of $\mathcal{Z}$ gives

$$
\frac{\partial \mathcal{Z}_{\boldsymbol{\pi}}(S)}{\partial \pi_{\ell}}=\sum_{S^{\prime}}-E_{\ell}\left(S^{\prime}\right) \cdot \mathbb{P}\left(S^{\prime} \mid \boldsymbol{\pi}\right) \cdot \frac{\mathcal{Z}_{\pi}}{\pi_{\ell}}=-\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right) \cdot \frac{\mathcal{Z}_{\pi}}{\pi_{\ell}} .
$$

From these expressions, we conclude that

$$
\begin{aligned}
\frac{\partial \mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right)}{\partial \pi_{\ell}} & =\sum_{S} E_{\ell}(S) \cdot \frac{\partial \mathbb{P}(S \mid \boldsymbol{\pi})}{\partial \pi_{\ell}} \\
& =\sum_{S} E_{\ell}(S)\left(\frac{\frac{\partial \mathcal{B}_{\pi}(S)}{\partial \pi_{\ell}}}{\mathcal{Z}_{\boldsymbol{\pi}}}-\frac{\frac{\partial \mathcal{Z}_{\pi}}{\partial \pi_{\ell}} \cdot \mathcal{B}_{\boldsymbol{\pi}}(S)}{\mathcal{Z}_{\pi}^{2}}\right) \\
& =\sum_{S} E_{\ell}(S)\left(\frac{-E_{\ell}(S) \cdot \mathbb{P}(S \mid \boldsymbol{\pi}) \cdot \frac{\mathcal{Z}_{\boldsymbol{\pi}}}{\pi_{\ell}}}{\mathcal{Z}_{\boldsymbol{\pi}}}+\frac{\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right) \cdot \frac{\mathcal{Z}_{\pi}}{\pi_{\ell}} \cdot \mathcal{B}_{\boldsymbol{\pi}}(S)}{\mathcal{Z}_{\boldsymbol{\pi}}^{2}}\right) \\
& =\sum_{S}-\frac{E_{\ell}(S)^{2} \cdot \mathbb{P}(S \mid \boldsymbol{\pi})}{\pi_{\ell}}+\frac{\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right)}{\pi_{\ell}} \sum_{S} E_{\ell}(S) \cdot \mathbb{P}(S \mid \boldsymbol{\pi}) \\
& =-\frac{\mathbb{E}\left(E_{\ell}^{2} \mid \boldsymbol{\pi}\right)-\mathbb{E}\left(E_{\ell} \mid \boldsymbol{\pi}\right)^{2}}{\pi_{\ell}}
\end{aligned}
$$

In the numerator of the above expression, one recognizes the variance of the distribution of $E_{\ell}$. Remark that a variance is always non-negative and, in our case, also strictly positive for $\pi, \pi_{\ell}>0$, as soon as there exist at least two distinct sequences $S$ and $S^{\prime}$ such that $E_{\ell}(S) \neq E_{\ell}\left(S^{\prime}\right)$. Moreover, weights are always positive so the partial derivative in $\pi_{\ell}$ is always positive. Ultimately, it is always possible to increase (resp. decrease) the expected free energy of a structure by simply decreasing (resp. increasing) its weight, supporting our weight optimization procedure.

## H Detailed result of quality analysis

N/A values correspond to data that could not be obtained by the time of this submission for two main reasons: In the case of the initial sampling (left columns), they correspond to instances which, in conjunction with an expressive energy model, resulted in very high tree-width, leading to unreasonable memory requirements incompatible with our available computing resources; The case of missing values after optimization (right columns), they indicate situations where the initial optimization took too long ( $\approx 1$ day) and was killed.
