Belief Propagation for Subgraph Detection with Imperfect Side-information

Arun Kadavankandy, Konstantin Avrachenkov, Laura Cottatellucci and Rajesh Sundaresan

Abstract—We propose a local message passing algorithm based on Belief Propagation (BP) to detect a small hidden Erdős-Rényi (ER) subgraph embedded in a larger sparse ER random graph in the presence of side-information. We consider side-information in the form of revealed subgraph nodes called cues, some of which may be erroneous. Namely, the revealed nodes may not all belong to the subgraph, and it is not known to the algorithm a priori which cues are correct and which are incorrect. We show that asymptotically as the graph size tends to infinity, the expected fraction of misclassified nodes approaches zero for any positive value of a parameter \(\lambda\), which represents the effective Signal-to-Noise Ratio of the detection problem. Previous works on subgraph detection using BP without side-information showed that BP fails to recover the subgraph when \(\lambda < 1/e\). Our results thus demonstrate the substantial gains in having even a small amount of side-information.

Index Terms—Subgraph detection, Erdős-Rényi, Belief Propagation

I. INTRODUCTION AND RELATED LITERATURE

Hidden community detection in a graph is an important problem with many applications in Information Theory, Signal Processing and Machine Learning. A hidden community could be in the form of a group of densely linked nodes in a large sparser network. Many real-world problems such as fraud detection in auction networks [1] and webgraphs [2] can be formulated as dense subgraph detection problems. The interested reader is referred to [3] for an expository survey.

In this work, we follow a model-based approach, where we model the hidden community as a small Erdős-Rényi (ER) graph of size \(K\) with a large edge probability embedded in a larger ER graph of size \(n\) with a smaller edge probability. Let \(\rho\) be the edge probability among the subgraph nodes and \(q\) be the edge probability outside, such that \(p > q\). Henceforth, we denote this random graph by \(G(K,n,p,q)\). This model was proposed in [4] to study anomalous transactions in a computer network. It is a special case of the Stochastic Block Model (SBM) extensively studied recently in community detection and also in Information Theory [5]–[7].

The hidden subgraph problem as well as its variations such as hidden clique detection has been considered in several recent works, e.g. [8]–[14]. In [12] the author analyzed the setting where \(p = a/n,q = b/n\) and \(K = \kappa n\) where \(a, b, K\) are constants independent of \(n\). This is an example of a diluted random graph, i.e., a graph where the average degree is a constant irrespective of the graph size. It was shown in [12] that a Maximum Likelihood (ML) detector achieves vanishing asymptotic probability of error for any positive \(\lambda\), defined as a function of the graph parameters as below:

\[
\lambda = \frac{K^2(p-q)^2}{(n-K)q}. \tag{1}
\]

This parameter can be interpreted as an effective Signal-to-Noise Ratio (SNR). In [12] the author also analyzed the performance of subgraph detection using Belief Propagation (BP) and showed that BP recovers the subgraph with vanishing error only if \(\lambda > 1/e\) and fails otherwise. In [14] the authors analyzed BP in a more general parameter setting where \(K = o(n)\) and also proved that BP fails when \(\lambda < 1/e\), whereas ML detection succeeds when \(\lambda = \Omega(K/n\log(n/K))\). It can be concluded that BP, which is near-linear in computational complexity on diluted graphs, is strictly inferior to ML detection, which has exponential complexity with respect to (w.r.t.) \(n\), for the problem of subgraph detection. The above works on subgraph detection on \(G(K,n,p,q)\) do not take into account any form of side-information.

In this work, we study the influence of side-information on the detectability threshold of BP for subgraph detection when this side-information may be erroneous. The side-information we consider is in the form of cues, i.e., we are revealed a few nodes that belong to the hidden community. BP with side-information for community partitioning for two-block and general \(k\)-block SBM has been studied in [15], [16]. BP with exact cues for subgraph detection was studied recently in [17]. However, this algorithm does not take into account the possibility that the cues may be erroneous, i.e., some of the cued nodes may be erroneously assigned to the subgraph.

Our Contributions: We develop a BP based subgraph detection algorithm that uses imperfect side-information. The accuracy of cues is quantified by a parameter \(\beta\), which we define as the expected fraction of correct cues. We then analyse the error performance of this algorithm on \(G(K,n,p,q)\) with \(p = a/n,q = b/n\), \(K = \kappa n\) and derive the asymptotic distributions of the BP messages in the large degree regime where \(a,b \to \infty\). Using these distributions, we derive an expression for the asymptotic misclassification rate of the algorithm and show that in the limit when \(K/n = \kappa \to 0\), the error rate tends to zero for any \(\lambda > 0\) as long as \(\beta > 0\). A similar result was shown in [17] for exact cues. Thus, we show that the presence of side-information removes the detectability threshold found in BP without side-information and hence any small amount of side-information greatly improves the performance of the algorithm.

Notation: We denote the cardinality of a set \(S\) by |\(S\)| and for two sets \(A,B\) \(A \Delta B\) denotes the set difference given by \((A \setminus B) \cup (B \setminus A)^c\), where \(A^c\) denotes the complement of set \(A\). We denote by \(\text{Poi} (\lambda)\) the Poisson distribution with mean \(\lambda\) and by \(N(\mu, \sigma^2)\) the Gaussian distribution with mean \(\mu\) and variance \(\sigma^2\). Also, \(X \sim f(x)\) means that the random variable (rv) \(X\) has distribution \(f(x)\). Lastly, \(P(E)\) denotes the probability of an event \(E\) and \(E\) denotes the expectation operator.

The rest of the paper is organised as follows. In Section II we introduce the system model. In Section III we present our algorithm and a sketch of its derivation. In Section IV we analyse the asymptotic error rate of the algorithm, in Section V we provide some simulation results, and conclude the paper in Section VI.

\(^{1}\)Here and in the rest of the paper \(e\) represents the base of the natural logarithm.
II. SYSTEM MODEL

Consider a realization $G = (V, E)$ of $G(K, n, p, q)$ where $V = \{1, 2, \ldots, n\}$ is the set of nodes and $E \subset V \times V$ is the set of edges. Community $S \subset V$ is chosen from $V$ uniformly from all subsets of size $K$. Then edges are added between any pair of nodes $i, j$ independently of all other pairs such that $P((i, j) \in E | i, j \in S) = p$ and $P((i, j) \in E | i \in S, j \notin S) = P((i, j) \in E | i \notin S, j \in S) = q$, with $p > q$. In other words, edges between subgraph nodes appear with probability $p$, and all other edges appear with probability $q$. We can denote subgraph membership using a function $\sigma : V \rightarrow \{0, 1\}^n$ such that $\sigma_i = 1$ if $i \in S$ and $\sigma_i = 0$ if $i \notin S$. A subset of nodes is labelled as cues. We use a function $c : V \rightarrow \{0, 1\}^n$ to denote cue membership, i.e., $c_i = 1$, if $i$ is a cue and $c_i = 0$ otherwise. To describe the side-information, we define two parameters $\alpha$ and $\beta$ as follows:

$$\alpha = \frac{E(\sum_{i=1}^{n} \chi(c_i=1))}{K} = \frac{n\beta}{K},$$

where $\chi$ is the indicator function, and

$$\beta = P(\sigma_i = 1|c_i = 1),$$

for any node $i$. Thus, $\alpha$ is the expected fraction of cues w.r.t. the subgraph size and $\beta$ represents the quality of cues, i.e., how likely a node is to be in a subgraph if it is a cue. We then choose cues such that $P(c_i = 1|\sigma_i = 1) = \alpha \beta$ and $P(c_i = 1|\sigma_i = 0) = \frac{K\alpha(1-\beta)}{n-K}$ so that (2) and (3) hold.

III. BELIEF PROPAGATION ALGORITHM

In this section, we present our algorithm and an outline of its derivation. The optimal algorithm that minimises the average probability of node misclassification, and hence the expected number of misclassified nodes, is the MAP (Maximum a Posteriori Probability) detector [13]. For every node $i$, this algorithm computes the likelihood function

$$R_i = \log \left( \frac{P(G, C|\sigma_i = 1)}{P(G, C|\sigma_i = 0)} \right)$$

and it declares a node as belonging to the subgraph if $R_i > \log \left( \frac{P(\sigma_i = 0)}{P(\sigma_i = 1)} \right)$, where $G$ denotes the graph realization and $C$ is the cue information in the form of the function $c$. This algorithm would need the knowledge of the entire graph and moreover has exponential complexity for calculating the likelihood function w.r.t. $\sigma_i$. Therefore we focus on Belief Propagation, which approximates $R_i$ using the observation of only local neighbourhoods of nodes. In a graph $G$, we define a $t$-hop neighbourhood $G^t_i$ of a node $i$ as the set of nodes that can be reached from $i$ by traversing at most $t$ links. Then the set of neighbours of $i$, which we denote $\delta_i$, is equal to $G^1_i$. BP is a recursive algorithm that uses $G^t_i$ and the cue information contained therein, denoted by $C^t_i$, to compute the following likelihood function at each node locally by aggregating messages sent by its neighbours:

$$R^t_i = \log \left( \frac{P(G^t_i, c^t_i, C^t_i|\sigma_i = 1)}{P(G^t_i, c^t_i, C^t_i|\sigma_i = 0)} \right).$$  

(4)

To derive the BP recursions, we exploit the fact that $G(K, n, p, q)$ in a small neighbourhood of a node resembles a tree, i.e., it is locally tree-like. This was formalized in [14, Lemma 15] by means of a coupling formulation between $G^t_i$ and a specially constructed Galton-Watson (G-W) tree $T^t_i$ with Poisson degrees rooted at $i$. We denote by $\tau_i$ the subgraph label of node $i$ on the tree, whereas $\sigma_i$ is the label on the original graph.

Lemma 1 [14, Lemma 15] For $G(K, n, p, q)$ with $p = a/n$ and $q = b/n$, if $t = o(\log(n))$ there exists a coupling such that $(G^t_i, \sigma^t_i, C^t_i) = (T^t_i, \tau^t_i, C^t_i)$ with probability $1 - n^{-1+o(1)}$, where $\tau^t$ represents the labels on the tree $T^t_i$ and $\sigma^t$ denotes the labels on $G^t_i$.

The proof proceeds by showing that the probability of having a cycle in $G^t_i$ tends to zero and that the degrees of nodes, which are Bernoulli rvs, converge in total-variation distance to Poisson rvs as $n \rightarrow \infty$.

We describe briefly the construction of the tree $T^t_i$ to aid in the understanding of the derivation of our algorithm. The label $\tau_i$ of node $i$ is 1 with probability $K/n$ and zero with probability $1 - K/n$. Node $i$ has $N_i$ children, where $N_i$ is distributed as a Poisson rv with mean $d_1 = Kp + (n - K)q = \kappa a + (1 - \kappa) b$ if $\tau_i = 1$ or mean $d_0 = nq = nb$ if $\tau_i = 0$. If $\tau_i = 1$, each child $j$ of node $i$ is assigned a label $\tau_j$ such that $\tau_j = 1$ with probability $Kp/d_1$ and 0 with probability $1 - Kp/d_1$. If on the other hand $\tau_i = 0$, $\tau_j = 1$ with probability $Kq/d_0$ and $\tau_j = 0$ with probability $1 - Kq/d_0$. Therefore, the number of children of $i$ with label 1 is Poisson distributed with mean $Kp$ if $\tau_i = 1$ and mean $Kq$ if $\tau_i = 0$. Similarly, the number of children with label 0 is Poisson distributed with mean $(n - K)q$. At any level of the tree, a node $j$ is labelled a cue such that

$$P(c_i = 1|\tau_j = 1) = \frac{\alpha \beta}{K},$$

$$P(c_i = 1|\tau_j = 0) = \frac{K\alpha(1-\beta)}{n-K}.$$  

(5)

This construction then continues up to depth $t$. An interesting consequence of the tree coupling is the fact that given the label at node $i$, the subtrees $T^t_{i,j}$ rooted at the children $j$ are jointly independent. Therefore the likelihood ratios at the subtrees can be computed independently and then transmitted up to node $i$ where they are combined. The tree coupling along with likelihood computation on trees is used by BP to simplify the methodology for calculating the likelihood function $R^t_i$. Algorithm 1 is the resulting BP algorithm.

Algorithm 1 BP with imperfect cues

1: Initialize: Set $R^0_{i\rightarrow j}$ to 0, for all $(i,j) \in E$. Let $t_f < \frac{\log(n)}{\log(np)} + 1$. Set $t = 0$.

2: For all directed pairs $(j,i) \in E$,

$$R^{t+1}_{i \rightarrow j} = -K(p-q) + h_j + \sum_{l \in \delta_j, l \neq i} \log \left( \frac{\exp(R^t_{l \rightarrow j} - \nu)(p/q) + 1}{\exp(R^t_{l \rightarrow j} - \nu) + 1} \right),$$

(6)

where $\nu = \log(\frac{n-K}{n})$ and $h_j$ is defined in (9).

3: Increment $t$. If $t < t_f$ go back to 2, else go to 4.

4: Compute $R^t_u$ for every $u \in V \setminus C$ as follows:

$$R^{t+1}_u = -K(p-q) + h_i + \sum_{l \in \delta_i} \log \left( \frac{\exp(R^t_{l \rightarrow u} - \nu)(p/q) + 1}{\exp(R^t_{l \rightarrow u} - \nu) + 1} \right)$$

(7)

5: Output $\hat{S}$ as $K$ set of nodes in $V$ with the largest values of $R^t_u$.

Here we provide a brief sketch of its derivation. Recall the definition of $R^t_i$ given in (4). Assuming that up to depth $t$ the neighbourhood $G^t_i$ has no cycles, i.e., the tree-coupling
holds, we can split the log-likelihood ratio in three parts as follows.

\[
R_i^t = \log \left( \frac{\mathbb{P}(G_i^t, C_i^t | \sigma_i = 1)}{\mathbb{P}(G_i^t, C_i^t | \sigma_i = 0)} \right) + \log \left( \frac{\mathbb{P}(C_i | \sigma_i = 1)}{\mathbb{P}(C_i | \sigma_i = 0)} \right) \\
= \sum_{j \in \delta i} \log \left( \frac{\mathbb{P}(G_j^{t-1}, \{u\}, C_j^{t-1}, c_j | \sigma_i = 1)}{\mathbb{P}(G_j^{t-1}, \{u\}, C_j^{t-1}, c_j | \sigma_i = 0)} \right) + \log \left( \frac{\mathbb{P}(N_i | \sigma_i = 1)}{\mathbb{P}(N_i | \sigma_i = 0)} \right) + h_i.
\]

(8)

Here we used the independence property of \(|\delta i| = N_i\) and the subtrees \(G_j^{t-1}\). The second term in (8) captures the randomness of \(|\delta i|\). Also \(h_i = \log \left( \frac{\mathbb{P}(C_i | \sigma_i = 1)}{\mathbb{P}(C_i | \sigma_i = 0)} \right)\) is given by

\[
h_i = \begin{cases} 
\log \left( \frac{\beta(n-K)}{(n-K)\lambda(K)} \right) & \text{if } i \in C \\
\log \left( \frac{(1-\alpha)(n-K)}{(n-K)\lambda(K+\alpha\beta)} \right) & \text{otherwise}.
\end{cases}
\]

(9)

This above term captures our faith in the cues; notice that when \(\beta = 1\), \(h_i = \infty\) if \(i\) is a cue. In this case the cues are exact and hence Algorithm 1 becomes the same as the BP algorithm for exact cues from [17]. Observe that we can expand \(\mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_i = 1)\) as below

\[
\mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_i = 1) = \mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j, \sigma_j = 1 | \sigma_i = 1) + \mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j, \sigma_j = 0 | \sigma_i = 1) \\
= Kp/d_1 \mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_j = 1) + \frac{(n-K)q}{d_1} \mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_j = 0)
\]

where we used the fact that \(\mathbb{P}(\sigma_j = 1 | \sigma_i = 1) = Kp/d_1\) and \(\mathbb{P}(\sigma_j = 0 | \sigma_i = 1) = (n-K)q/d_1\). Similarly we can expand \(\mathbb{P}(C_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_i = 0)\) and defining \(R_j^{t-1} = \log \left( \frac{\mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_i = 1)}{\mathbb{P}(G_j^{t-1}\{u\}, C_j^{t-1}, c_j | \sigma_i = 0)} \right)\) we obtain the recursion (7) to update the beliefs \(R_i^t\). The recursion to update \(R_j^{t-1}\) can be obtained by repeating the same steps. It can be verified that the computational complexity of this algorithm is \(O(t/E)\).

IV. ASYMPTOTIC ERROR ANALYSIS

In this section we analyse the distributions of the messages \(R_i^t\) of a node \(i\) in the limit where the graph size \(n \to \infty\). In our analysis we assume that \(p = a/n, q = b/n\) and \(K = kn\). We derive the conditional distributions of the messages \(R_i^t\) for a finite \(t\) given \(\sigma_i = 0\) and \(\sigma_i = 1\). In this limit the tree assumption holds by Lemma 1. Let \(F_i^t\) be such that \(R_i^t = F_i^t + h_i\). Then, it can be seen from (7) that \(F_i^t\) satisfies the following recursion

\[
F_i^{t+1} = -K(p-q) + \sum_{i \in \delta i} f(F_i^t + h_i),
\]

(10)

where \(f(x) = \log \left( \frac{e^{(x-v)/\tau}+1}{e^{(x-v)/\tau}+1} \right)\). Let \(\Psi_0^t, \Psi_1^t\) be the rvs that have the asymptotic conditional distribution of \(F_i^t\) given \(\sigma_i = 0\) and \(\sigma_i = 1\) respectively. Then, by studying the recursion (10) on the G-W tree \(T_i^t\) we can conclude that \(\Psi_0^t, \Psi_1^t\) satisfy the following recursive distributional equations

\[
\Psi_0^{t+1} \overset{D}{=} -\kappa(a-b) + \sum_{i=0}^{L_{01c}} f(\Psi_1^t + B_c) + \sum_{i=0}^{L_{00n}} f(\Psi_0^t + B_c) \\
\Psi_1^{t+1} \overset{D}{=} -\kappa(a-b) + \sum_{i=0}^{L_{11c}} f(\Psi_1^t + B_c) + \sum_{i=0}^{L_{10n}} f(\Psi_0^t + B_c)
\]

where \(D\) represents equality in distribution, and the random sums are such that \(L_{01c} \sim \text{Poi}(\kappa b(1-\alpha\beta)), L_{00n} \sim \text{Poi}(\kappa b(1-\alpha\beta)), L_{11c} \sim \text{Poi}(\kappa b(1-\alpha\beta)), L_{10n} \sim \text{Poi}(\kappa b(1-\alpha\beta)), L_{00n} \sim \text{Poi}(\kappa b(1-\alpha\beta))\) represents the number of its uncued children with label 0. Similarly for a node with label 1, \(L_{11c} \sim \text{Poi}(\kappa b(1-\alpha\beta))\) represents the number of its uncued children with label 1. Finally \(L_{10n} \sim \text{Poi}(\kappa b(1-\alpha\beta))\) represents the number of its children with label 0 that are not cues. Here we used the tree construction and (5) to derive the means of the Poisson rvs. In addition, \(B_c = h_i\) when \(c_i = 1\) and \(B_n = h_i\) when \(c_i = 0\) as given in (9) and \(\Psi_0^t, \Psi_1^t\) are iid rvs with the same distribution as \(\Psi_0^t\) and \(\Psi_1^t\) respectively. Based on the above recursions we can analyse the distributions of \(\Psi_0^t, \Psi_1^t\) in the large degree regime when \(a, b \to \infty\). In the following proposition, we present the asymptotic distributions in this regime.

**Proposition 1** Consider the distribution of BP messages \(R_i^t\) when \(n \to \infty\). In the high degree regime where \(b = \kappa n\) tends to \(\infty\) such that \(\lambda = K^c(p-q)^2 = \kappa^2(a-b)^2\) and \(K = kn\) are held fixed, for any \(t > 0\), the random variables \(\Psi_0^t\) and \(\Psi_1^t\) converge in distribution to \(\Gamma_0^t\) and \(\Gamma_1^t\), which have Gaussian distributions given as follows

\[
\Gamma_0^t \sim N(-\mu^{(t)}/2, \mu^{(t)}) \\
\Gamma_1^t \sim N(\mu^{(t)}/2, \mu^{(t)}),
\]

where \(\mu^{(t)}\) satisfies the following recursion with \(\mu^{(0)} = 0\)

\[
\mu^{(t+1)} = \alpha \beta^2 \lambda E \left( \frac{1 - \kappa}{(\beta + 1 - \beta) e^{(-\mu^{(t)}/2 - \sqrt{\mu^{(t)}} z)}} \right) + (1 - \alpha \beta)^2 \lambda E \left( \frac{1 - \kappa}{(\kappa (1 - \beta) + 1 - \kappa - \alpha \kappa + \alpha \kappa \beta) e^{(-\mu^{(t)}/2 - \sqrt{\mu^{(t)}} z)}} \right)
\]

(11)
with $\lambda$ as defined in (1) and the expectation is w.r.t. $Z \sim \mathcal{N}(0,1)$. The messages $\Gamma_i^u$ for any node $u$ given $\{\sigma_u = i\}$ for $i \in \{0,1\}$ are asymptotically distributed as $\Gamma_i^u + B_c$ if $u$ is a cue, and $\Gamma_i^u + B_0$ if $u$ is not a cue.

The proof can be found in the technical report [18]. Next, we present our main result on the asymptotic error rate of Algorithm 1.

**Theorem 1** For any $\lambda > 0$, $\alpha > 0$, $\beta > 0$, 
\[
\lim_{b \to \infty} \lim_{n \to \infty} \frac{\mathbb{E}(|\tilde{S}|)}{K} = 0.
\]

**Sketch of the Proof:** We only provide a sketch of the proof; the missing details can be found in the technical report [18]. Let $0 < \alpha, \beta < 1$. Using the conditional asymptotic distributions from Proposition 1, we can derive the expected error rate of the following local MAP detector, which uses the local likelihood functions $\Gamma_i^u$. Its output $\tilde{S}_0$ is given as
\[
\tilde{S}_0 = \{i : \Gamma_i^u > \nu\},
\]
where $\nu = \log \left(\frac{P(\sigma_u = 0)}{P(\sigma_u = 1)}\right) = \log \left(\frac{1-\kappa}{\kappa}\right)$. Note that, in contrast, Algorithm 1 outputs $\tilde{S}$, which is the set of $K$ nodes with $K$ largest values of $\Gamma_i^u$. However the expected number of misclassified nodes $\mathbb{E}(|\tilde{S}|)$ can be related to $\mathbb{E}(|\tilde{S}_0|)$ as follows:
\[
\mathbb{E}(|\tilde{S}|) \leq 2\mathbb{E}(|\tilde{S}_0|).
\]
In what follows, we give a bound for $\mathbb{E}(|\tilde{S}_0|)$. By analyzing the recursion (11) we can show that for any $t > 0$,
\[
\alpha \beta = \lambda \left(\frac{1-\kappa}{\kappa}\right).
\]
Note that the lower bound above is useful only when $\alpha$ and $\beta$ are non-zero, hence why it is important to have non-trivial side-information. Let $\Gamma_{i,j}^u$ be the rv that has the conditional asymptotic distribution, as $n \to \infty$, $b \to \infty$, of $R_i^u$ given $\{\sigma_u = i, c_u = j\}$ for $i,j \in \{0,1\}$ for any node $u$. Then from Proposition 1 we have
\[
\Gamma_{0,0}^i \sim \mathcal{N} \left(-\mu^0 + B_n, \mu^0 \right)
\]
\[
\Gamma_{0,1}^i \sim \mathcal{N} \left(-\mu^0 + B_c, \mu^0 \right)
\]
\[
\Gamma_{1,0}^i \sim \mathcal{N} \left(\mu^0 + B_n, \mu^0 \right)
\]
\[
\Gamma_{1,1}^i \sim \mathcal{N} \left(\mu^0 + B_c, \mu^0 \right).
\]
Let $p_e(u)$ be the average probability of error of the detector in (12) for any node $u$. It can be written as
\[
p_e(u) = p_e(u|\sigma_u = 0, c_u = 0)P(\sigma_u = 0, c_u = 0) +
p_e(u|\sigma_u = 0, c_u = 1)P(\sigma_u = 0, c_u = 1) + p_e(u|\sigma_u = 1, c_u = 0)P(\sigma_u = 1, c_u = 0) + p_e(u|\sigma_u = 1, c_u = 1)P(\sigma_u = 1, c_u = 1),
\]
where $p_e(u|\sigma_u = 0, c_u = 0)$ denotes the probability that a non-subgraph node $u$ is classified by the algorithm as a subgraph node if it is not a cue, and similarly for the other terms. Consequently,
\[
\lim_{b \to \infty} \lim_{n \to \infty} \mathbb{E}(|\tilde{S}_0|) = 0.
\]

In short, Theorem 1 states that the expected fraction of misclassified subgraph nodes tends to zero as $K/n \to 0$ for any $\lambda > 0$ as long as $\alpha > 0$ and $\beta > 0$, i.e., if there exists non-trivial side-information. This form of recovery is called weak recovery [14]. In [12], [14] it is shown that BP without side-information achieves weak-recovery when $\lambda > 1/e$ and fails to achieve weak recovery when $\lambda < 1/e$ whereas global ML detection succeeds for all $\lambda > 0$. Thus we have shown that side-information enables us to remove the threshold phenomenon that exists in BP for subgraph detection without side-information.

We also compare our algorithm with a naive algorithm defined as follows. Pick nodes with $K$ largest value of $d_i(C)$ defined as $d_i(C) = |\{(i,j) : j \in C\}|$. The question to ask is: How does this method fare against BP? We can determine the distribution of $d_i(C)$ in the limit as $n \to \infty$ using the coupling formulation in Lemma 1 and it is given as
\[
d_i(C) \sim \begin{cases} 
P(\kappa \alpha \beta(1 + (\rho - 1)\beta)) & \text{if } i \in S \\
P(\kappa \alpha \beta) & \text{if } i \notin S,
\end{cases}
\]

\[3Q(x) \leq \exp(-x^2/2).
\]
where $\rho := a/b$.

Clearly, for any constant $\lambda$ we have that $\rho \to 1$ as $b \to \infty$ and thus, this method of detection will fail to correctly classify the subgraph nodes for any constant $\lambda$, and is thus inferior to the BP algorithm. In the next section, we compare the two methods on simulated graphs.

V. NUMERICAL EXPERIMENTS

In our first experiment, we compare Algorithm 1 against BP algorithm for exact cues given in [17], in the presence of inaccurate cues. We also compare our algorithm with the simple algorithm detailed in (15), denoted as Algorithm 2 in the figure. The numerical results we obtain demonstrate that BP for exact cues is not robust with respect to erroneous cues, and hence there is a need for adopting an algorithm that allows for inexact or erroneous cues. We simulate $G(n,p,q)$ with $n = 10^3$, $K = 200$, $p = 0.05$, and $q = 0.0046$. We fix $\alpha = 0.1$ and compute the error metric $\sum_{\epsilon \in X} (\sigma_\epsilon = 0) / K$, i.e., the fraction of wrongly classified subgraph nodes. In Figure 1 we plot this metric against $\beta$.

In the second set of experiments we study the impact of side-information on BP error performance. To this end we compare the performance of BP algorithm without side-information given in [12] to our algorithm. We simulate a graph of size $10^4$, $q = 0.0140$ and $K = 330$ for different values of $\beta$ by varying $p$. In Figure 2 we plot the metric $\sum_{\epsilon \in X} (\sigma_\epsilon = 0) / K$ against $\beta$ for different values of $\alpha$. For comparison we plot the error rate of random guessing. The results demonstrate that having side-information provides significant improvements over standard BP.

VI. CONCLUSIONS

In this work we investigated how a subgraph detection algorithm using cues based on Belief Propagation can be modified to take into account imperfect side-information, i.e., the fact that some of the cues can be wrong. We presented a new algorithm based on Belief Propagation that uses imperfect side-information and showed that it achieves weak recovery whenever $\lambda > 0$, in the limiting regime where $a, b \to \infty$, thus showing that BP with side-information does not exhibit the threshold phenomenon found in BP without side-information.
