Technical Report n° 0494 — December 20, 2017 — 21 pages

Abstract: This technical report presents the methodology and the numerical results for 21 stock prices under the assumption they follow a Drifted Geometric Oscillating Brownian motion model. Such a model takes leverage and mean-reversion effects into account. Ce rapport completes the article *A threshold model for local volatility: evidence of leverage and mean reversion effects on historical data*.

Key-words: Financial Mathematics; geometric Oscillating Brownian motion; Realized volatility estimator; Maximum likelihood; mean-reversion; leverage effect

1. Introduction

In [7], we present a simple model — the Geometric Oscillating Brownian motion (GOBM) — which extends the Geometric Brownian motion (also called the Black & Scholes model) by allowing the volatility and the appreciation rate to be piecewise constant. This model can be seen as a continuous time extension of a Self-Exciting Threshold AutoRegressive (SETAR) time series [13, 14]. It is also an alternative to the one proposed by L. Esquivel and P. Mota [3] which is based on a regime switching with a thin layer which prevents immediate switching.

In [3], their model have been tested against the stock prices of 21 assets on the period 2005-2009. Their method is derived from the one used in time series [14].

In this technical report, we present the numerical results which we obtain on the same 21 stocks prices as in [3] based on the estimators of the volatility and appreciation rates which studied in [8] and [9].

These numerical results are summarized and commented in [7]. Therefore, we only give a technical presentation of the estimators and the raw results.

Outline. In Section 2, we present the different estimators we use. In Section 3, we give the numerical results.

2. Theoretical results

2.1. Estimation of the model

Notations: $x^+ = \max\{x, 0\}$, $x^- = \max\{-x, 0\}$.

2.1.1. The model

The price S is solution to the SDE

$$S_t = x + \int_0^t \sigma(S_s) S_s dB_s + \int_0^t \mu(S_s) S_s ds, \quad (1)$$

where, for threshold $m \in \mathbb{R}$,

$$\sigma(x) = \begin{cases} \sigma_+ & \text{if } x \geq m, \\ \sigma_- & \text{if } x < m \end{cases}, \text{ and } \mu(x) = \begin{cases} \mu_+ & \text{if } x \geq m, \\ \mu_- & \text{if } x < m. \end{cases} \quad (2)$$

The *log-price* $X = \log(S)$ satisfies the SDE

$$X_t = x + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds, \quad (3)$$

with

$$r = \log(m) \text{ and } b(x) = \begin{cases} b_+ = \mu_+ - \sigma_+^2/2 & \text{if } x \geq r, \\ b_- = \mu_- - \sigma_-^2/2 & \text{if } x < r. \end{cases} \quad (4)$$

2.1.2. The parameters

There are 5 parameters to identify on the log-price:

- $\sigma_- > 0$, the volatility below the negative side,
- $\sigma_+ > 0$, the volatility above the threshold,
- $b_- \in \mathbb{R}$, the drift below the threshold,
- $b_+ \in \mathbb{R}$, the drift above the threshold,
- $r \in \mathbb{R}$, the threshold.

2.1.3. The estimation procedure

Given the daily observations $\{X_i\}_{i=0}^n$ of the log-price (the time step between two observations is $\Delta t = 1$), the estimation is performed in several steps:

- (1) The range of the log-price X is split in values $\{r_i\}_{i=1,\dots,M}$ that are used as possible threshold. We use $M = 60$.
- (2) For each r_i , we set $Y = X - r_i$ so that Y is an OBM with a threshold at 0. We estimate the occupation times Λ_+ and Λ_- by

$$\Lambda_+(i) = \Delta t \sum_{i=0}^{n-1} \mathbf{1}_{Y_i \geq 0} \text{ and } \Lambda_-(i) = \Delta t \sum_{i=0}^{n-1} \mathbf{1}_{Y_i \leq 0}. \quad (5)$$

We estimate the volatilities σ_+ and σ_- by

$$\sigma_+(i) = \left(\frac{\sum_{j=0}^{n-1} (Y_{j+1} - Y_j) \times (Y_{j+1}^+ - Y_j^+)}{\Lambda_+(i)} \right)^{1/2}$$

$$\text{and } \sigma_-(i) = \left(\frac{\sum_{j=0}^{n-1} (Y_{j+1} - Y_j) \times (Y_{j+1}^- - Y_j^-)}{\Lambda_-(i)} \right)^{1/2}.$$

We estimate the local time L of Y at 0 at time n by

$$L(i) = \frac{3\sqrt{\pi}}{2\sqrt{2}} \frac{(\sigma_+(i) + \sigma_-(i))}{\sigma_+(i)\sigma_-(i)} \sum_{j=0}^{n-1} (Y_{j+1}^- - Y_j^-) \times (Y_{j+1}^+ - Y_j^+). \quad (6)$$

We also estimate the drifts $b_+(i)$ and $b_-(i)$ by

$$b_+(i) = \frac{-\frac{1}{2}L(i) - Y_n^+ - Y_0^+}{\Lambda_+(i)} \text{ and } b_-(i) = \frac{\frac{1}{2}L(i) - Y_n^- - Y_0^-}{\Lambda_-(i)}.$$

- (3) For each threshold r_i , we compute

$$\ell(i) = \widehat{\text{Log-Lik}}(X, b_+(i), b_-(i), \sigma_+(i), \sigma_-(i), r_i)$$

given by (10) below. We select the value $\hat{i}$ of i for which $\ell(i)$ is maximal. This follows the principle of the Akaike Information Principle [1] (the number of parameters is the same whatever r_i).

- (4) The estimated values of $(r, \sigma_+, \sigma_-, b_+, b_-)$ are then

$$(\hat{r}, \hat{\sigma}_+, \hat{\sigma}_-, \hat{b}_+, \hat{b}_-) = (r_{\hat{i}}, \sigma_+(\hat{i}), \sigma_-(\hat{i}), b_+(\hat{i}), b_-(\hat{i})).$$

2.1.4. The detrended time series

Our observations $\{\xi_i\}_{i=0}^n$ with time step $\Delta t = 1$ forms a time series. Given $\beta = (\beta_+, \beta_-) \in \mathbb{R}^2$, we define the *detrended time series* by

$$\xi_i^{\triangleleft\beta} = \xi_i - \beta_+ \mathbf{1}_{\xi_i \geq 0} \Delta t - \beta_- \mathbf{1}_{\xi_i < 0} \Delta t. \quad (7)$$

2.1.5. Approximation of the log-likelihood

With

$$\Theta(x) = \mathbf{1}_{x \geq 0} \sigma_+ + \mathbf{1}_{x < 0} \sigma_- \text{ and } \Upsilon(x) = x/\Theta(x),$$

the solution to (3) is transformed into $Y_t = \Upsilon(X_t - r)$ the solution to

$$Y_t = Y_0 + B_t + \int_0^t \frac{b(Y_s)}{\sigma(Y_s)} ds + \theta L_t^0(Y) \text{ with } \theta = \frac{\sigma_- - \sigma_+}{\sigma_- + \sigma_+}, \quad (8)$$

where $L_t^0(Y)$ is the symmetric local at 0 of Y . The SDE (8) is the one of a drifted Skew Brownian motion. When $b_+ = b_- = 0$, then Y is a Skew Brownian motion of parameter $\theta \in (-1, 1)$. Its density is given by

$$p_{\text{SBM}}(t, x, y) = \frac{1}{\sqrt{2\pi t}} \left(\exp\left(\frac{-(x-y)^2}{2t}\right) + \text{sgn}(y)\theta \exp\left(\frac{-(|x| + |y|)^2}{2t}\right) \right). \quad (9)$$

Eq. (9) gives a simple formula for the transition density of X without drift (see also [5]):

$$p(t, x, y; \sigma_+, \sigma_-) = p_{\text{SBM}}\left(t, \frac{x}{\Theta(x)}, \frac{y}{\Theta(y)}\right) \frac{1}{\Theta(y)}.$$

For our data, the ratio b/σ is small (see 3.3). Since the time step between the observations is $\Delta t = 1$, this means that the volatility is the main factor explaining variations of the log-prices. For an estimated drift $\beta = (\beta_+, \beta_-)$, an estimated volatility (s_+, s_-) and a choice ρ of the threshold, the log-likelihood is approximated¹ by

$$\widehat{\text{Log-Lik}}(X, \beta_+, \beta_-, s_+, s_-, \rho) = \sum_{i=1}^n \log p(\Delta t, (X - \rho)_{i-1}^{\triangleleft(\beta_+, \beta_-)}, (X - \rho)_i^{\triangleleft(\beta_+, \beta_-)}; s_+, s_-), \quad (10)$$

where $(X - \rho)^{\triangleleft(\beta_+, \beta_-)}$ is the detrended time series defined by (7) for the observations $\{X_i\}_{i=0}^n$.

2.1.6. Approximation of the skewness parameter

As asserted above, when $b = 0$, then $Y = \Upsilon(X)$ is a Skew Brownian motion (SBM) of parameter $\theta = (\sigma_- - \sigma_+)/(\sigma_- + \sigma_+)$.

The observations $\{X_i\}_{i=0}^n$ are transformed into (with $\Delta t = 1$),

$$Y_i = \frac{X_i - r - \hat{b}_+ \mathbf{1}_{X_i \geq 0} \Delta t - \hat{b}_- \mathbf{1}_{X_i < 0} \Delta t}{\hat{\sigma}_+ \mathbf{1}_{X_i \geq 0} + \hat{\sigma}_- \mathbf{1}_{X_i < 0}}.$$

Hence, if X follows an OBM, then the dynamic of the Y should be close to the ones of a SBM of parameter θ .

¹The approximation comes from the fact that the detrended time series is not exactly the observations of a Skew Brownian motion. Besides, only an approximation of the drift is used.

Given the discrete observations of a SBM of parameter θ , and owing the explicit expression (9) of its density transition function, the parameter θ is easily estimated by θ_{MLE} through a Maximum Likelihood Estimation (MLE). It is shown in [6] that θ_{MLE} is a consistent estimator of θ . When $\theta = 0$ (the Brownian motion), then the rate of convergence is $n^{1/4}$. It is conjectured that this rate of convergence still holds for $\theta \neq 0$.

In Sect. 3.10, we estimate θ_{MLE} which we compare to the predicted value $\hat{\theta} = (\hat{\sigma}_- - \hat{\sigma}_+)/(\hat{\sigma}_- + \hat{\sigma}_+)$. We have a good agreement for several of the stocks. A bad agreement could be explain by the following facts:

- The quality of the estimation depends on the local time (which we relate to the number of crossings) which is sometimes very low, leading to a bad estimation.
- The stock log-price does not follows an OBM. An extra local time could be added for example to take a *directional predictability* into account (See [2] for example). We note however that θ_{MLE} is sometimes negative, which seems to contradict a directional predictability in which the (log-)prices tend to rise.

2.1.7. Testing the equality of the two volatilities

In this section, it is assumed that $b_- = b_+ = 0$, that is, the drift terms vanish.

From the data, we consider the hypotheses

- (H_0) (null hypothesis) $\sigma_- = \sigma_+$;
- (H_1) (alternative hypothesis) $\sigma_- \neq \sigma_+$.

For the sake of simplicity, let us set

$$S_{\pm} = \sigma_{\pm}^2, \quad S_{\pm}^n = (\hat{\sigma}_{\pm}^n)^2, \quad \mathbf{S} = \begin{bmatrix} S_- \\ S_+ \end{bmatrix} \quad \text{and} \quad \mathbf{S}^n = \begin{bmatrix} S_-^n \\ S_+^n \end{bmatrix}.$$

We also define

$$O_{\pm} = \frac{1}{T} \int_0^T \mathbf{1}_{\pm X_s \geq 0} ds \quad \text{and} \quad O_{\pm}^n = \frac{1}{n} \sum_{j=0}^{n-1} \mathbf{1}_{\pm X_j \geq 0}.$$

the normalized positive (resp. negative) occupation time.

The following convergence results was established

$$\sqrt{n}(\mathbf{S}^n - \mathbf{S}) \xrightarrow[n \rightarrow \infty]{\text{stably}} \sqrt{2} \begin{bmatrix} S_- \frac{G_-}{\sqrt{O_-}} \\ S_+ \frac{G_+}{\sqrt{O_+}} \end{bmatrix} = M\mathbf{G} \quad \text{with} \quad M = \sqrt{2} \begin{bmatrix} S_-/\sqrt{O_-} & 0 \\ 0 & S_+/\sqrt{O_+} \end{bmatrix}, \quad (11)$$

where $\mathbf{G} = [G_- \quad G_+]^T \sim \mathcal{N}(0, \text{Id})$ is a Gaussian vector independent from the process X .

The matrix M is approximated by

$$M^n = \sqrt{2} \begin{bmatrix} S_-^n/\sqrt{O_-^n} & 0 \\ 0 & S_+^n/\sqrt{O_+^n} \end{bmatrix}.$$

Thanks to the isotropy of the Gaussian vector $\mathbf{G}$, we define for a level of confidence α the quantity q_{α} by $\mathbb{P}(|\mathbf{G}| \leq q_{\alpha}) = 1 - \alpha$. The random variable $|\mathbf{G}|^2$ follows a χ^2 distribution with two degrees of freedom so that q_{α} is easily computed by the R command `qchisq`.

Our *acceptance region* of level α is then the ellipsis

$$\mathcal{R}_{\alpha} = \left\{ \mathbf{S}^n + \frac{q_{\alpha}}{\sqrt{n}} M^n \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix} \mid \theta \in [0, 2\pi) \right\}.$$

Our **rule of decision** is to reject the Null Hypothesis (H_0) if the diagonal line $s : [0, +\infty) \mapsto (s, s)$ does not cross $\mathcal{R}_{\alpha}$.

2.2. The data

2.2.1. The stocks

The data are the same as the one in [11]. The daily quotations of the stocks are downloaded from the Web site Yahoo Finance [15]. The dates range from 01/02/2005 to 30/11/2009. Clearly, the time series for KO differs from the one in [11].

GOOG	Google	HP	Hewlett-Packard	AAPL	Apple
ADBE	Adobe	CA	CA	C	CitiGroup
KO	Coca-cola	CSCO	Cisco	IBM	IBM
JPM	JP Morgan	MCD	McDonalds	SBUX	Starbucks
PM	Philip Morris	PG	P & G	PFE	Pfizer
PCG	PG&E	NYT	New-York Times	MSFT	Microsoft
MSI	Motorola	MON	Monsanto	AMZN	Amazon

The number of samples is 1217 for each stock, excepted for PM where there are only 432 samples.

2.2.2. Software

All the estimations have been performed using the **R** software [12].

3. Numerical results

3.1. The estimated values

Estimated parameters for the GOBM model: $\sigma_{\pm}$ is the daily volatility $\mu_{\pm} = b_{\pm} + \sigma_{\pm}^2/2$ is the daily mean return rate, $b_{\pm}$ is the drift of the log-price and *signs* are the respective signs of b_{-} , b_{+} (a $+-$ indicates a mean-reversion effect).

3.2. Normalized Occupation times and normalized number of crossings

When there is no drift, the positive and negative occupation times are known to follow a variant of the Arc-Sine distribution [5, 10]. With a drift, this distribution changes. However, it is expected that the normalized positive occupation time $\Lambda(T)/T$ up to time T is “close” to 0 or 1.

The normalized number of crossings is related to the local time. Actually, for the Skew Brownian motion, a consistent local time estimator may be built from this quantity [6].

3.3. The detrended time series

The different parameters are estimated for the trended and the detrended time series. The estimations are similar. The stock for which there is a difference in (σ_-, σ_+) in MON, for which the log-likelihood is flat on a rather large range (See 3.5).

3.4. Prices of the stocks

The prices are expressed in USD. The horizontal dashed line is the threshold m .

3.5. The log-likelihood

The dashed vertical lines are at $r(\hat{i})$, the threshold which maximizes the log-likelihood.

The dashed horizontal lines are at the log-likelihood of the Geometric Brownian motion.

3.6. Estimation of the volatilities in function of the threshold

The estimated volatilities $\sigma_+(i)$ (marked by $\oplus$) and $\sigma_-(i)$ (marked by $\ominus$) are plotted in function of the possible thresholds $r(i)$ for the log-prices.

The dashed vertical lines are at $r(\hat{i})$, the threshold which maximizes the log-likelihood.

3.7. Estimation of the drift in function of the threshold

The estimated drift $b_+(i)$ (marked by $\oplus$) and $b_-(i)$ (marked by $\ominus$) are plotted in function of the possible thresholds $r(i)$ for the log-prices.

The dashed vertical lines are at $r(\hat{i})$, the threshold which maximizes the log-likelihood.

3.8. Non parametric estimation of the volatility

The dashed horizontal lines are at σ_- and σ_+ , the estimated volatilities.

The dashed vertical lines are at $r(\hat{v})$, the threshold which maximizes the log-likelihood.

The non parametric estimation is performed using `ksdiff` of the R package `sde` [4], which implement de Nadaraya-Watson estimator.

3.9. Non parametric estimation of the drift

The dashed horizontal lines are at b_- and b_+ , the estimated volatilities.

The dashed vertical lines are at $r(\hat{i})$, the threshold which maximizes the log-likelihood.

The non parametric estimation is performed using `ksdrift` of the R package `sde` [4], which implement de Nadaraya-Watson estimator.

3.10. Estimation of the skewness parameter

The maximum likelihood estimator θ_{MLE} for the parameter $\theta \in (-1, 1)$ of the SBM is then estimated and compared to $\theta = (\hat{\sigma}_- - \hat{\sigma}_+)/(\hat{\sigma}_- + \hat{\sigma}_+)$.

The data are classified according to the range of the normalized number n_c of crossings
 $\ominus$: $[0, 1\%]$ $\odot$: $[1\%, 2\%]$ $\oplus$: $[2\%, 3\%]$. This classification gives an indication on how big is the local time [6], hence on the quality of the estimator.

3.11. Testing the equality of the two volatilities

The 95 %-confidence regions for testing the null hypothesis $\sigma_- = \sigma_+$ are plotted for each of the 21 stocks. They are plotted with respect to (σ_-^2, σ_+^2) , hence the scale, and to (σ_-, σ_+) .

The dashed line is the diagonal line $x \mapsto x$.

Only one confidence ellipsis is crossed by this line, the one for PCG, but this is due to a very small negative occupation time.

A. The Girsanov weight

In this appendix, we show that the Girsanov weight may be estimated as well, thanks to the particular structure of our drift and volatility.

The drift of the centered log-price $Y = X - r$ could be removed using a Girsanov transform. More precisely, for a function Ξ on the space $\mathcal{C}([0, T]; \mathbb{R})$ of continuous functions, $\mathbb{E}[G\Xi(Y)] = \mathbb{E}[\Xi(\check{Y})]$, where $\check{Y}$ is the solution to

$$\check{Y}_t = x + \int_0^t \sigma(\check{Y}_s) dB'_s$$

and $G = \exp\left(-\int_0^T \Gamma(Y_s) dB_s - \frac{1}{2} \int_0^T \Gamma^2(Y_s) ds\right)$ with $\Gamma(x) = \frac{b(x)}{\sigma(x)}$,

for a Brownian motion B' .

With the Itô-Tanaka formula,

$$Y_t^+ = Y_0^+ + \sigma_+ \int_0^t \mathbf{1}_{Y_s \geq 0} dB_s + b_+ \Lambda(t) + \frac{1}{2} L_t^0(Y), \quad (12)$$

$$Y_t^- = Y_0^- - \sigma_- \int_0^t \mathbf{1}_{Y_s \leq 0} dB_s - b_-(t - \Lambda(t)) + \frac{1}{2} L_t^0(Y) \quad (13)$$

where $\Lambda(t) = \int_0^t \mathbf{1}_{Y_s \geq 0} ds$ and $\{L_t^0(Y)\}_{t \geq 0}$ is the symmetric local time of Y at 0. Multiplying (12) by b_+/σ_+^2 and (13) by b_-/σ_-^2 leads to

$$\frac{b_+}{\sigma_+^2} Y_t^+ = \frac{b_+}{\sigma_+^2} Y_0^+ + \int_0^t \mathbf{1}_{Y_s \geq 0} \Gamma(Y_s) dB_s + \frac{b_+^2}{\sigma_+^2} \Lambda(t) + \frac{b_+}{2\sigma_+^2} L_t^0(Y),$$

and

$$\frac{b_-}{\sigma_-^2} Y_t^- = \frac{b_-}{\sigma_-^2} Y_0^- - \int_0^t \mathbf{1}_{Y_s \geq 0} \Gamma(Y_s) dB_s - \frac{b_-^2}{\sigma_-^2} (t - \Lambda(t)) + \frac{b_-}{2\sigma_-^2} L_t^0(Y).$$

Hence,

$$\begin{aligned} \int_0^t \Gamma(Y_s) dB_s &= \frac{b_+}{\sigma_+^2} Y_t^+ - \frac{b_+}{\sigma_+^2} Y_0^+ - \frac{b_-}{\sigma_-^2} Y_t^- + \frac{b_-}{\sigma_-^2} Y_0^- \\ &\quad - \frac{b_+^2}{\sigma_+^2} \Lambda(t) - \frac{b_-^2}{\sigma_-^2} (t - \Lambda(t)) - \left(\frac{b_+}{2\sigma_+^2} + \frac{b_-}{2\sigma_-^2} \right) L_t^0(Y). \end{aligned}$$

On the other hand,

$$\frac{1}{2} \int_0^t \Gamma(Y_s)^2 ds = \frac{b_+^2}{2\sigma_+^2} \Lambda(t) + \frac{b_-^2}{2\sigma_-^2} (t - \Lambda(t)).$$

It is then possible to estimate the Girsanov weight from the estimations of $\sigma_{\pm}$, $b_{\pm}$ and $\Lambda(t)$ and $L_t^0(Y)$. The quantities $\Lambda(t)$ and $L_t^0(Y)$ can be approximated as in (5) and (6).
