Optimal Multiphase Investment Strategies for Influencing Opinions in a Social Network

Swapnil Dhamal, Walid Ben-Ameur, Tijani Chahed, and Eitan Altman

Abstract—We study the problem of two competing camps aiming to maximize the adoption of their respective opinions, by optimally investing in nodes of a social network in multiple phases. The final opinion of a node in a phase acts as its biased opinion in the following phase. Using an extension of Friedkin-Johnsen model, we formulate the camps’ utility functions, which we show to involve what can be interpreted as multiphase Katz centrality. We hence present optimal investment strategies of the camps, and the loss incurred if myopic strategy is employed. Simulations affirm that nodes attributing higher weightage to their biases need to be invested in initial phase. The extended version of this paper analyzes a setting where a camp’s influence on a node depends on the node’s bias; we show existence and polynomial time computability of Nash equilibrium.

Index Terms—Social networks, opinion dynamics, multiple phases, Katz centrality, zero-sum games, Nash equilibrium

I. INTRODUCTION

We consider two competing camps with positive and negative opinion values (referred to as good and bad camps respectively), aiming to maximize the adoption of their respective opinions in a social network. With the opinion adoption quantified as the sum of opinion values of all nodes [1], [2], the good camp aims to maximize this sum while the bad camp aims to minimize it. Since nodes update their opinions based on their neighbors’ opinions [3], [4], a camp would want to influence the opinions of influential nodes by investing on them. Thus given a budget constraint, the strategy of a camp comprises of: how much to invest and on which nodes, in presence of a competing camp which also invests strategically.

A. Motivation

In Friedkin-Johnsen model of opinion dynamics [5], [6], every node holds a bias in opinion. This bias plays a critical role in determining a node’s final opinion, and consequently the opinions of its neighbors, and hence that of its neighbors’ neighbors, and so on. If nodes give significant weightage to their biases, the camps would want to influence these biases. This could be achieved by campaigning in multiple phases, wherein a node’s opinion at the end of a phase acts as its biased opinion in the next phase. With the possibility of multiphase campaigning, a camp could not only decide which nodes to invest on, but also how much to invest in each phase (hence, how to split its budget across phases).

The original publication appears as short paper in the 2018 International Conference on Autonomous Agents and Multiagent Systems.

B. Related Work

Problems related to maximizing opinion adoption in social networks have been extensively studied in the literature [7], [3], [8]. A primary task in such problems is to determine influential nodes, which has been an important research area in the multiagent systems community [9], [10], [11], [12]. The competitive setting has resulted in several game theoretic studies [13], [14], [15]. Specific to analytically tractable models such as DeGroot and Friedkin-Johnsen, there have been studies to determine optimal investments on influential nodes [16], [17], [2]. Our work extends these studies to multiple phases by determining the influential nodes in different phases, and how much they should be invested on in a given phase.

There have been a few studies on adaptive selection of influential nodes in multiple phases [18], [19], [20], [21], [22], [23], [24]. A survey of such adaptive methods is presented in [25]. An empirical study on optimal budget splitting between two phases is presented in [26], which is extended to multiple phases in [27]. While the reasoning behind using multiple phases in these studies is to adaptively select nodes based on previous observations, we use them for influencing nodes’ biases; this necessitates a very different treatment.

II. OUR MODEL

We represent social network as a weighted directed graph, with set of nodes $N$. Our model can be viewed as a multiphase extension of [28]. Table I presents the notation. In our setting, the bias of node $i$ in phase $q$ is $v_{iq}$, which is the opinion value of node $i$ at the conclusion of phase $q-1$. Since the influence of good camp on node $i$ in phase $q$ would be an increasing function of its investment $x_{iq}$ and weightage $w_{ig}$, we assume the influence to be $+v_{iq}x_{iq}$ so as to maintain linearity of Friedkin-Johnsen model. Similarly, $-w_{ib}y_{ib}$ is the influence

of bad camp (negative opinion) on node \( i \). Considering budget constraints, the camps should invest in the \( p \) phases such that 
\[
\sum_{q=1}^{p} \sum_{i \in N} x_{q}^{i} \leq k_{g} \quad \text{and} \quad \sum_{q=1}^{p} \sum_{i \in N} y_{q}^{i} \leq k_{b}.
\]

Let \( w \) be the matrix consisting of weights \( w_{ij} \). Let \( v^{(0)}, v^{(q)}, w^{0}, w_{g}, w_{b}, x^{(q)}, y^{(q)} \) be the vectors consisting of elements \( v_{i}^{(q)}, v_{j}^{(q)}, w_{ij}, w_{ig}, w_{ib}, x_{i}^{(q)}, y_{j}^{(q)} \), respectively. Vectors \( x^{(q)}, y^{(q)} \), \( v^{(q-1)} \) are static throughout a phase \( q \), while \( v^{(q)} \) gets updated in the dynamics. Let \( o \) denote Hadamard product: \( (a \odot b)_{i} = a_{i}b_{i} \). Hence, generalizing the Friedkin-Johnsen update rule to multiphase setting and accounting for camps’ investments, the update rule in phase \( q \) is:
\[
\forall i \in N : v_{i}^{(q)} \leftarrow w_{i}^{0} v_{i}^{(q-1)} + \sum_{j \in N} w_{ij} v_{j}^{(q)} + w_{ig} x_{i}^{(q)} - w_{ib} y_{i}^{(q)}
\]

\[
\iff v^{(q)} \leftarrow w^{0} \odot v^{(q-1)} + w_{g} \odot x^{(q)} - w_{b} \odot y^{(q)}
\]

With \( \sum_{j \in N} |w_{ij}| < 1 \), dynamics in phase \( q \) converges to [29]:
\[
v^{(q)} = (I - w)^{-1}(w^{0} \odot v^{(q-1)} + w_{g} \odot x^{(q)} - w_{b} \odot y^{(q)}) \quad (1)
\]

### III. Problem Formulation

We first derive an expression for \( \sum_{i \in N} v_{i}^{(p)} \), the sum of opinion values of the nodes at the end of terminal phase \( p \). Let \( (I - w)^{-1} = \Delta \). Let \( \Delta^{(1)} = \sum_{j \in N} \Delta_{ji} \) and \( \Delta^{(t)} = \sum_{j \in N} \Delta_{ji}^{(t-1)} w_{ij}^{0} \Delta_{ji} \). That is, \( \Delta^{(1)} = \Delta^{T} T \) and \( \Delta^{(t)} = \Delta^{T} T^{(t-1)} \odot w^{0} \). It can be shown that, premultiplying Equation (1) by \( T \) for \( q = p \), and solving the recursion, we get:
\[
\sum_{i \in N} v_{i}^{(p)} = \sum_{i \in N} v_{i}^{(0)} + \sum_{q=1}^{p} \sum_{j \in N} \sum_{i \in N} w_{ij} x_{i}^{(q)} - w_{ib} y_{i}^{(q)}
\]

### A. Multiphase Katz Centrality

\( \Delta^{(1)} \) resembles Katz centrality of node \( i \) [30], capturing its influencing power over other nodes in a single phase setting (corresponds to terminal phase in multiphase setting). However, the effectiveness of node \( i \) with \( t \) phases to go \( (r_{j}^{(t)}) \), depends on its influencing power over those nodes \( j \) (\( \Delta_{ji} \)), which would give good weightage to their bias in the next phase \( (w_{ij}^{0}) \), and also have good effectiveness in the next phase with \( t - 1 \) phases to go \( (r_{j}^{(t-1)}) \). This is captured by \( r_{j}^{(t)} = \sum_{j \in N} r_{j}^{(t-1)} w_{ij}^{0} \Delta_{ji} \). Since \( r_{j}^{(t)} \) quantifies \( i \)'s influence looking \( t \) phases ahead, it can be interpreted as the \( t \)-phase Katz centrality.

### B. The Problem

Here \( (x^{(q)})^{p}_{q=1} \) and \( (y^{(q)})^{p}_{q=1} \) are the respective strategies of the good and bad camps. Given an investment strategy profile \( ((x^{(q)})^{p}_{q=1}, (y^{(q)})^{p}_{q=1}) \), let \( u_{g}(((x^{(q)})^{p}_{q=1}, (y^{(q)})^{p}_{q=1})) \) be the utility of good camp and \( u_{b}(((x^{(q)})^{p}_{q=1}, (y^{(q)})^{p}_{q=1})) \) be the utility of bad camp. The good camp aims to maximize (2), while the bad camp simultaneously aims to minimize it. Hence the problem is:

\[
\text{Find Nash equilibrium, given that}
\]

\[
\begin{align*}
&u_{g} \left( \left( (x^{(q)})^{p}_{q=1}, (y^{(q)})^{p}_{q=1} \right) \right) = \sum_{i \in N} v_{i}^{(p)} \\
&u_{b} \left( \left( (x^{(q)})^{p}_{q=1}, (y^{(q)})^{p}_{q=1} \right) \right) = - \sum_{i \in N} v_{i}^{(p)}
\end{align*}
\]

subject to
\[
\sum_{q=1}^{p} \sum_{i \in N} x_{q}^{i} \leq k_{g}, \sum_{q=1}^{p} \sum_{i \in N} y_{q}^{i} \leq k_{b}
\]

\( \forall q \in \{1, \ldots, p\} \forall i \in N : x_{i}^{(q)}, y_{i}^{(q)} \geq 0 \)

### C. Optimal Investment Strategies

Since the optimization terms with respect to different variables are decoupled in Equation (2), the optimal strategies of camps are mutually independent. For the good camp, we order the terms \{\( w_{ij}^{p-q+1} \)\} \( i \in N, q=1, \ldots, p \) in descending order. If the investment allowed per node is unbounded, its optimal strategy is to invest \( k_{g} \) on node \( i^{*} \) in phase \( q^{*} \), where \( (i^{*}, q^{*}) = \arg \max_{(i,p)} w_{ij}^{p} \) \( (k_{g} \text{ investment if this value is non-positive}) \). If the investment per node is bounded by \( \mathcal{U} \), the \( (i, p) \) pairs are chosen one-by-one according to the aforementioned descending ordering, and invested on \( \mathcal{U} \) each, until budget \( k_{g} \) is exhausted. The optimal strategy of the bad camp is analogous.

### IV. Simulation Results

For 2 phases on NetHEPT dataset (15,233 nodes) [8], [31], [32], Figure 1(a) presents optimal budget allotted for phase 1 as a function of \( w_{ij}^{0} \) (assuming equal \( w_{ij}^{0}, \forall j \in N \)) with \( k_{g} = k_{b} = 100 \) \( \mathcal{U} = 1 \) and \( v_{i}^{(0)} = 0 \), \( \forall i \in N \). Detailed simulation setup is provided in [29]. For low \( w_{ij}^{0} \), the optimal strategy of camps is to invest almost entirely in phase 2, since the effect of phase 1 would diminish considerably in phase 2. The value \( v_{i}^{(2)} = \sum_{j \in N} r_{j}^{(1)} w_{ij}^{0} \Delta_{ji} \) would be significant only if \( i \) influences nodes \( j \) with significant values of \( w_{ij}^{0} \). So investing in phase 1 would be advantageous only if nodes have significant \( w_{ij}^{0} \). The slight non-monotonicity of plots is explained in [29]. General observations indicate that a high range of \( w_{ij}^{0} \) makes it advantageous for camps to invest in phase 1, so as to effectively influence the biases in phase 2. The reasoning generalizes to more than 2 phases.
Figure 1(b) illustrates the loss incurred by bad camp when it is myopic (perceiving its utility as $- \sum_{i \in N} v_{1}^{(1)}$ instead of $- \sum_{i \in N} v_{1}^{(2)}$), while the good camp is farsighted (considering no bound on investment per node). A myopic bad camp would invest its entire budget in phase 1, and with the same reasoning as above, it would incur more loss for lower values of $u_{jj}^{0}$ (ref. [29] for details).

V. IN EXTENDED VERSION OF THIS PAPER
The extended version of this paper [29] analyzes a setting where a node attributes higher weightage to the camp more aligned with its bias. The camps’ strategies are no longer mutually independent; we show existence and polynomial time computability of Nash equilibrium.
