#### Abstract

This paper considers distributed vertex-coloring in broadcast/receive networks suffering from conflicts and collisions. (A collision occurs when, during the same round, messages are sent to the same process by too many neighbors; a conflict occurs when a process and one of its neighbors broadcast during the same round.) More specifically, the paper focuses on multi-channel networks, in which a process may either broadcast a message to its neighbors or receive a message from at most $\gamma$ of them. The paper first provides a new upper bound on the corresponding graph coloring problem (known as frugal coloring) in general graphs; proposes an exact bound for the problem in trees; presents a deterministic, parallel, color-optimal, collision- and conflict-free distributed coloring algorithm for trees; proves the correctness of this algorithm; and finally evaluates experimentally its performance using simulations that show our solution clearly outperforms a reference protocol for distributed TDMA slot-allocation.

Index Terms-Distributed algorithms, Message-passing, Broadcast/receive communication, Synchronous systems, Multi-coloring, Vertex coloring, TDMA slot allocation

## 1 Introduction

Distributed graph coloring is one of the fundamental problems of distributed computing research [3], [4], [7], [9]. It is particularly well adapted to situations in which resources (in the form of colors) must be allocated to processes (or nodes ${ }^{1}$ ). In spite of its fundamental nature, however, very few works have investigated distributed coloring in the presence of a communication adversary, i.e. when neighboring nodes in the communication graph are not guaranteed to be able to communicate reliably in all communication rounds.

In this paper we consider one such problem, which arises when allocating time slots in a multi-channel Time Division Medium Access (TDMA) wireless network. In such networks, a node with a single transceiver is unable to simultaneously receive and send at the same time (a situation known as a conflict), but may however simultaneous receive messages from up to $\gamma$ neighbors without collision (a situation occurring when $\gamma+1$ or more neighbors of the same node attempt to broadcast simultaneously).

Conflicts and collisions can be avoided by allocating specific time-slots and specific channels to individual nodes, while taking into account neighboring relationships in the communication graph. In a multi-channel network, these constraints can be modeled as a specific vertex graph coloring problem, known as frugal coloring [12], [19], in which

[^0]1. We use both words interchangeably, with a preference for process when describing an algorithmic behavior.
the same color (representing a time slot) might be allocated up to $\gamma$ times (the number of available channels) in a node's neighborhood. Performing this channel allocation reliably and efficiently in a distributed manner is however challenging: because channels have not been allocated yet, extra care must be taken to avoid conflicts and collisions during the allocation procedure.

Existing solutions to this problem tend to be either probabilistic [11], [13], [17], [25], or to ignore collisions and conflicts altogether [5], [10]. In this paper, we aim to improve on this situation, by seeking deterministic distributed solutions to frugal coloring (and hence to the TDMA slot allocation problem), that tolerate conflicts and collisions (a problem we have called Frugal Coloring under Conflicts and Collisions, or F3C for short). Determinism is important, as it deliver more predictable solutions, that tend to terminate faster (a point confirmed by our experimental evaluation). Robustness to conflicts and collisions is essential in practice, to allow solutions to be used in real systems in which a TDMA schedule has not been computed yet.

To solve F3C, we make the following contributions ( $\Delta$ is the tree's maximum degree, and $\gamma$ the number of available communication channels):

- We provide an upper bound on the minimum number of colors necessary to solve F3C in a general communication graph. This bound complements existing asymptotic bounds, while putting no constraints on $\Delta$.
- We prove that $\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$ colors are both necessary and sufficient to solve F3C in trees.
- We propose and prove the correctness of a deterministic, color-optimal, parallel, collision- and conflict-free, distributed protocol that solves F3C on trees in $O\left(d\left\lceil\frac{\Delta}{\gamma}\right\rceil\right)$ steps,
where $d$ is the tree's depth.
In the following, we first present some background and motivate the F3C problem (Sec. 2). We then describe the underlying system model (Sec. 3), before formally defining the F3C problem (Sec. 4). We then present an upper bound on the minimal number of colors $K$ necessary to solve F3C in general graphs, and a lower bound on $K$ in trees (Sec. 5). We then present our algorithm which solves F3C in trees (Sec. 6) and prove it (Sec. 7). We conclude in Section 9, and provide some prospective remarks.

## 2 Background and Problem

### 2.1 Distributed coloring in wireless networks

A large number of works [3], [5], [9], [10], [11], [13], [17] have proposed distributed vertex coloring algorithms applicable to wireless networks. Unfortunately, the coloring protocols proposed so far are either not robust to both conflicts and collisions [5], [10]; rely on probabilistic procedures to eventually converge to a solution with high probability [11], [13], [17], [25]; or adopt a sequential approach [9], in which one single process is communicating at a time, a particularly slow procedure. In terms of coloring, these protocols do not focus on multi-channel networks in which the same slot/color might be allocated several times among collisionprone neighbors.

Let us note, for the sake of completeness, that the multichannel allocation problem can also be modeled using other types of coloring, such as edge-coloring [26] (when focusing on wireless-links rather than on broadcast operations as we do), multicoloring [20] (when ignoring conflicts), or $t$ coloring [22] (when investigating cross-channel interference). These are crucial problems and contributions in their own right; they lie, however, out of the scope of the present work.

### 2.2 Distributed Frugal Coloring

A $\gamma$-frugal coloring [8], [12], [18], [19] is a particular type of graph coloring in which (i) two neighboring nodes must receive different colors (thus avoiding conflicts when mapping colors to time slots), and (ii) the same color might not be used more than $\gamma$ times in a node's neighborhood (thus avoiding collisions in an TDMA network using $\gamma$ channels).

Several important theoretical results exist on this type of coloring, but these are mostly limited to the asymptotic behavior of the minimal number of colors required to color a graph. Asymptotic means that these results typically hold for sufficiently large values of $\Delta$, the maximum degree of the graph. For instance, Molloy and Reed [19] showed that if a graph's maximum degree $\Delta$ is sufficiently large, a $(50 \ln \Delta / \ln \ln \Delta)$-frugal coloring exists with $\Delta+1$ colors (and that this value is in fact optimal for this frugality value in that some graphs cannot be colored with fewer colors). Hind et al. [12] showed that (i) for a sufficiently large $\Delta$ and any $\gamma \geq 1$, an $\gamma$-frugal coloring exists with at most max $\left\{(\gamma+1) \Delta,\left\lceil e^{3} \frac{\Delta^{1+1 / \gamma}}{\gamma}\right\rceil\right\}$ colors, and that (ii) for arbitrary large $\Delta$ there is a graph with maximum degree $\Delta$ that cannot be $\gamma$-frugally colored with fewer than $\frac{\Delta^{1+1 / \gamma}}{2 \gamma}$ colors. In the same vein, Molloy and Reed showed that if a graph's maximum degree $\Delta$ is larger than $\gamma^{\gamma}$ then an $\gamma$ frugal coloring exists with $16 \Delta^{1+\frac{1}{\gamma}}$ colors [18].

These results unfortunately do not translate easily to wireless networks. Assuming $\gamma=7$ channels for instance, the last result states the existence of a coloring (or schedule) with $\left\lceil 16 \times\left(7^{7}\right)^{1+\frac{1}{7}}\right\rceil=92,236,816$ colors (i.e. slots). Assuming a slot duration of 50 ms , this corresponds to an overall schedule of 53 days, an unpractical duration for many wireless applications. This growth is also overexponential, rising to 1242 days (or 3.4 years) for only $\gamma=8$ channels, 88 years for 9 channels, and 2,536 years for 10 channels.

Chung, Pettie and Su have proposed distributed algorithms [8] that realize some of the above frugal coloring results. Unfortunately, besides the unpracticality of the resulting coloring as a slot schedule, these algorithms have so far been probabilistic (they converge with high probability), and do not take into account collisions or conflicts in their distributed execution.

### 2.3 Problem and contributions

In contrast to the above results, we take a much more handson perspective in this work. We focus on the distributed deterministic frugal-coloring of realistic graphs, under adversarial communication constraints capturing conflicts and collisions, in a synchronous $\gamma$-channel wireless network. This problem, which we have termed Frugal Coloring under Conflicts and Collisions (F3C for short), has so far, and to the best of our knowledge, not yet been investigated.

Rather than targeting asymptotic results, we do not make any assumption on the maximum degree $\Delta$ of the graph, so that our results remain applicable to any network. We target deterministic algorithms in order to provide strong guarantees of rapid convergence in practical cases. Our overall goal is to solve the F3C problem for a given number of channels $\gamma$ with the smallest possible number of colors $K$ (thus reducing the overall size of the resulting slot allocation schedule), and in few synchronous rounds (avoiding whenever possible sequential solutions).

## 3 Synchronous Broadcast/Receive Model

### 3.1 Processes, initial knowledge, and graph

The system model consists of $n$ sequential processes denoted $p_{1}, \ldots, p_{n}$. These processes are organized in a communication graph that is connected and undirected, and reflects the limited communication range of wireless communications. When considering a process $p_{i}, 1 \leq i \leq n$, the integer $i$ is called its index. Indexes are not known to the processes. They are only a notation convenience used to distinguish processes and their local variables.

Each process $p_{i}$ has an identity $i d_{i}$, which is known only to itself and its neighbors (processes at distance 1 from it). The constant neighbors $i_{i}$ is a local set, known only to $p_{i}$, which contains the identities of $p_{i}$ 's neighbors (and only them). In order for a process $p_{i}$ not to confuse its neighbors, it is assumed that no two processes at distance less than or equal to 2 have the same identity. Two processes lying at a distance greater than 2 may however use the same identifier.
$\Delta_{i}$ denotes the degree of process $p_{i}$ (i.e. $\mid$ neighbors $s_{i} \mid$ ) and $\Delta$ denotes the maximal degree of the graph $\left(\max \left\{\Delta_{1}, \cdots, \Delta_{n}\right\}\right)$. While each process $p_{i}$ knows $\Delta_{i}$, no
process knows $\Delta$ (a process $p_{x}$ such that $\Delta_{x}=\Delta$ does not know that $\Delta_{x}$ is $\Delta$ ).

### 3.2 Timing model

Processing durations are assumed equal to 0 . This is justified by the following observations: (a) the duration of local computations is negligible with respect to message transfer delays, and (b) the processing duration of a message may be considered as a part of its transfer delay.

Communication is synchronous in the sense that there is an upper bound $D$ on message transfer delays, and this bound is known to all the processes (global knowledge) [1], [2], [16], [21], [23]. From an algorithm design point of view, we consider that there is a global clock, denoted $C L O C K$, which is increased by 1 , after each period of $D$ physical time units. Each value of $C L O C K$ defines what is usually called a time slot or a round.

### 3.3 Communication operations

Processes have access to two communication primitives denoted bcast() and receive(). A process $p_{i}$ invokes bcast TAG $(m s g)$ to send the message $m s g$ (whose type is TAG) to all its neighbors. We assume that a process only invokes bcast() at a beginning of a time slot (round). When a message TAG $(m s g)$ arrives at a process $p_{i}$, this process is immediately notified, and the operation receive() is executed to obtain and process the message. Hence, a message is always received and processed during the time slot (round) in which it was broadcast.

From a syntactic point of view, we use the following two 'when' notations to describe our algorithms, where predicate is a predicate involving $C L O C K$ and possibly local variables of the concerned process.

- when TAG $(m s g)$ is received do communication-free processing of the message.
- when predicate do code entailing at most one bcast invocation.

### 3.4 Conflicts and collisions with $\gamma$ channels

Each process shares the same communication medium (consisting of $\gamma$ wireless channels) with other nodes in its neighborhood. As a result, a process cannot receive messages simultaneously from more than $\gamma$ of its neighbors, and cannot broadcast and receive a message simultaneously. (These constraints capture networks in which nodes only have access to a single transceiver.) If communication is not controlled, message clashes, known as collisions and conflicts, may occur, preventing communication:

- A $\gamma$-collision occurs when more than $\gamma$ neighbors of a process $p_{i}$ invoke the operation bcast() during the same time slot (round).
- A conflict occurs when $p_{i}$ and one of its neighbors invoke bcast() during the same time slot (round).
We call a distributed algorithm that avoids these situations conflict- and $\gamma$-collision-free ( $C 2 \gamma$-free for short). In this work, we seek to produce a coloring that yields a C2 $\gamma$-free communication schedule, but we also want the distributed algorithm that constructs this coloring to be itself $\mathrm{C} 2 \gamma$-free.

Figure 1. Multi-coloring of a 21 -process 10-degree tree with the constraint $\gamma=3$ ( 5 colors). Nodes are allocated multiple colors when this assignment does not cause conflicts or $\gamma$-collisions. For instance, the left-most leaf is colored with $\{2,4\}$, as none of these colors have been allocated to its parents, which is colored with $\{0,1,3\}$.

## 4 The F3C Problem

### 4.1 Definition of the F3C problem

Let the color domain be the set of non-negative integers, and $\gamma$ and $K$ be two positive integers. Our aim is to assign a set of colors, denoted colors $_{i}$, to each vertex $p_{i}$, such that the following three properties are satisfied:

## - Conflict-freedom:

$\forall i, j:\left(p_{i}, p_{j}\right.$ are neighbors $) \Rightarrow$ colors $_{i} \cap$ colors $_{j}=\emptyset$.

- $\gamma$-Collision-freedom (or $\gamma$-frugality):
$\forall i, \forall c: \mid\left\{p_{j} \in\right.$ neighbors ${ }_{i}: c \in$ colors $\left._{j}\right\} \mid \leq \gamma$.
- Efficiency:

$$
\mid \cup_{1 \leq i \leq n} \text { colors }_{i} \mid \leq K
$$

The first property states the fundamental property of vertex coloring, namely, that any two neighbors are assigned distinct colors sets. The second property imposes an upper bound on the total number of colors that can be used in a process's neighborhood, a constraint also known as frugality [12], [19] for coloring algorithms. The two properties describe a $\gamma$-frugal coloring, except that here processes are assigned sets of colors (i.e. might be allocated several times slots), rather than individual colors.

In this paper we consider the problem of constructing a distributed algorithm that produces an $\gamma$-frugal coloring while facing conflicts and $\gamma$-collisions during its own execution, a problem we have termed $\gamma$-frugal Coloring under Conflicts and Collisions. We denote this problem F3C $(n, \gamma, K, 1)$ if each color set is constrained to be a singleton, and $\mathrm{F} 3 \mathrm{C}(n, \gamma, K, \geq 1)$ if there is no such restriction.

### 4.2 Example, particular instances, and use

An example of such a multi-coloring is given in Figure 1 on a network containing 21 processes, where $\Delta=10$, and with the constraint $\gamma=3$. Notice that $K=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1=5$ (the color set is $\{0,1,2,3,4\})$.

The problem instance $\operatorname{F3C}(n, \infty, K, 1)$ corresponds to the classical vertex-coloring problem under collisions, where at most $K$ different colors are allowed $(\gamma=\infty$ states that no process imposes a constraint on the colors of its neighbors, except that they must be different from its own color, and that collisions are absent). F3C $(n, \infty, K, \geq 1)$ produces what is called a multicoloring [20] (the sets of

Table 1
Notations used when manipulating multisets, balls, and spheres

| notation | meaning |
| :---: | :--- |
| $\operatorname{set}(M)$ | the underlying set of $M$, i.e. the set of elements |
|  | present at least once in $M$ |
| $\mathbf{1}_{M}(x)$ | the multiplicity of an element $x$ in the multiset $M$ |
| $\|M\|$ | the cardinality of $M$ |
| $M \otimes m$ | the $m$-multiple of $M$ |
| $A \uplus B$ | the multiset union of the multisets $A$ and $B$ |
| $A \cup B$ | the generalized set union of $A$ and $B$ |
| $A \backslash B$ | the generalized set difference of $A$ and $B$ |
| $A \cap B$ | the generalized set intersection of the multisets $A$ and |
|  | $B$ |
| $f(S)$ | image of the set $S$ by the function $f$ |
| $f[M]$ | multi-image of the multiset $M$ by the function $f$ |
| $\mathcal{S}_{r}^{p}$ | the sphere of radius $r$ centered on process $p$ |
| $\mathcal{B}_{r}^{p}$ | the ball of radius $r$ centered on process $p$ |

colors of two neighbors are simply requested to be disjoint), and $\operatorname{F3C}(n, 1, K, 1)$ captures the classical distance-2 coloring problem (vertices at distance $\leq 2$ have different colors).

The reader can easily see that $\mathrm{F} 3 \mathrm{C}(n, \gamma, K, \geq 1)$ captures the general coloring problem informally stated in the introduction. Once a process $p_{i}$ has been assigned a set of colors colors $_{i}$, at the application programming level, it is allowed to broadcast a message to neighbors at the rounds (time slots) corresponding to the values of $C L O C K$ such that $(C L O C K \bmod K) \in$ colors $_{i}$.

## 5 Impossibility, Lower Bound, and Upper Bound in Trees and General Graphs

### 5.1 An impossibility result

Generalizing a remark from [14] this section presents a lower bound on $K$ : neither $\mathrm{F} 3 \mathrm{C}(n, \gamma, K, 1)$, nor F3C $(n, \gamma, K, \geq 1)$, can be solved for $K \leq\left\lceil\frac{\Delta}{\gamma}\right\rceil$. The next sections will present an algorithm solving F3C $(n, \gamma, K, \geq 1)$ in trees in the synchronous model described in Section 3, and a proof of it. This algorithm is such $K=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$, and is consequently optimal with respect to the total number of colors.

Theorem 1. Neither $\operatorname{F3C}(n, \gamma, K, 1)$, nor $\operatorname{F3C}(n, \gamma, K, \geq 1)$ can be solved when $K \leq\left\lceil\frac{\Delta}{\gamma}\right\rceil$.

The proof of Theorem 1 follows from a simple counting argument on the number of colors required to color the neighborhood of a process with $\Delta$ neighbors. It is provided in the Appendix for space reasons.

Note that the resulting lower bound $K \geq\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$ necessary to solve F3C is valid for any graph. This contrasts for instance with the lower bound $\frac{\Delta^{1+1} \gamma_{\gamma}}{2 \gamma}$ proposed by Hind et al. [12], which holds for some graph of degree $\Delta$.

### 5.2 F3C( $n, \gamma, K, 1$ ) in a General Network

Theorem 2. $\Delta+\left\lfloor\frac{\Sigma}{\gamma}\right\rfloor+1$ colors are sufficient to solve $\operatorname{F3C}(n, \gamma, K, 1)$ in a general graph, where $\Sigma$ is the size of the largest sphere of radius 2 in G,i.e.,

$$
\Sigma=\max _{p \in \Pi}|\{q \in \Pi \mid \operatorname{dist}(p, q)=2\}|
$$

and $\operatorname{dist}(p, q)$ represents the hop-distance between two processes in $G$.

The above upper bound does not put any constraint on the maximum degree $\Delta$ of the graph, contrarily to earlier asymptotic results on $\gamma$-frugal coloring [12], [18], [19], [8]. It also uses $\Sigma$, the size of the largest sphere of radius 2 . It is in that respect complementary to these earlier bounds, which only rely on $\Delta$.
Proof The proof of Theorem 2 relies on the analysis of Algorithm 1, which implements a classical greedy sequential procedure that solves $\operatorname{F3C}(n, \gamma, K, 1)$ in a centralized shared memory model on an arbitrary connected graph $G$. Algorithm 1 and the proof use multisets ${ }^{2}$ with the following notations (summarized in Table 1):

- $\operatorname{set}(M)$ is the underlying set of $M$, the set of elements present at least once in $M$.
- $\mathbf{1}_{M}(x)$ is the multiplicity of an element $x$ in the multiset $M$. By construction we have

$$
\begin{equation*}
\mathbf{1}_{M}(x) \geq 1 \Longleftrightarrow x \in \operatorname{set}(M) \tag{1}
\end{equation*}
$$

- $|M|$ is the cardinality of $M$; in particular if $M$ has finite cardinality (which is the case of all sets and multisets used in the following)

$$
\begin{equation*}
|M|=\sum_{x \in \operatorname{set}(M)} \mathbf{1}_{M}(x) \tag{2}
\end{equation*}
$$

- $M \otimes m$, where $m$ is an integer, is the $m$-multiple of $M$, defined by

$$
\begin{equation*}
\mathbf{1}_{M \otimes m}(x)=\mathbf{1}_{M}(x) \times m . \tag{3}
\end{equation*}
$$

- $A \uplus B$ is the multiset union of the multisets $A$ and $B$, defined by

$$
\begin{equation*}
\mathbf{1}_{A \uplus B}(x)=\mathbf{1}_{A}(x)+\mathbf{1}_{B}(x) . \tag{4}
\end{equation*}
$$

- $A \cup B$ is the generalized set union of $A$ and $B$, defined by

$$
\begin{equation*}
\mathbf{1}_{A \cup B}(x)=\max \left\{\mathbf{1}_{A}(x), \mathbf{1}_{B}(x)\right\} \tag{5}
\end{equation*}
$$

- $A \backslash B$ is the generalized set difference of $A$ and $B$, defined by

$$
\begin{equation*}
\mathbf{1}_{A \backslash B}(x)=\max \left\{0, \mathbf{1}_{A}(x)-\mathbf{1}_{B}(x)\right\} \tag{6}
\end{equation*}
$$

- $A \cap B$ is the generalized set intersection of the multisets $A$ and $B$, defined by

$$
\begin{equation*}
\mathbf{1}_{A \cap B}(x)=\min \left\{\mathbf{1}_{A}(x), \mathbf{1}_{B}(x)\right\} \tag{7}
\end{equation*}
$$

We consider a set $S$ as a special case of a multiset in which all elements of $S$ have a multiplicity of 1:

$$
x \in S \Longleftrightarrow \mathbf{1}_{S}(x)=1
$$

Algorithm 1 iterates sequentially over all processes in the system (line 1). For each process $p_{i}$, the algorithm enumerates the colored tokens that are no longer available to $p_{i}$. First $\gamma$ colored tokens are counted in the multiset neighbors_toks for each neighbor of $p_{i}$ (line 2): in order to respect conflict freedom, these colors cannot be used to color $p_{i}$. The multiset siblings_toks at line 3 counts the number of times a color is used at distance 2 of $p_{i}$ : in order to respect $\gamma$-collision freedom, these colors can only be used for $p_{i}$ if
2. Differently from a set, a multiset (also called a bag), can contain several times the same element. Hence, while $\{a, b, c\}$ and $\{a, b, a, c, c, c\}$ are the same set, they are different multisets.

1 Init: Process colors are initialized to $\perp: \forall p_{i} \in \Pi:$ color $_{i}=\perp$.
for each $p_{i}$ in $\Pi$ do
neighbors_toks $\leftarrow\left\{\right.$ color $_{j}: p_{j} \in$ neighbors $\left._{i}\right\} \otimes \gamma ;$
siblings_toks $\leftarrow \bigcup_{p_{j} \in \text { neighbors }_{i}} \biguplus_{p_{k} \in \text { neighbors }_{j}}\left\{\right.$ color $\left._{k}\right\}$;
available_toks $\leftarrow \mathbb{N} \otimes \gamma \backslash$ (neighbors_toks $\cup$ siblings_toks); color $_{i} \leftarrow \min ($ set $($ available_toks $))$.

Algorithm 1: Sequential $\operatorname{F3C}(n, \gamma, K, 1)$ for a graph, based on a greedy strategy
they have been used less than $\gamma$ times in all neighborhoods neighbors $j_{j}$ to which $p_{i}$ belongs. Finally, neighbors_toks and siblings_toks are removed from $\mathbb{N} \otimes \gamma$, the multiset in which all natural numbers are present $\gamma$ times, and the lowest remaining available color is allocated to $p_{i}$ (line 4). During this iteration step, some of $p_{i}$ 's neighbors and neighbors of neighbors might not have been allocated a color yet: their color is formally equal to $\perp$, and eliminated at line 4 , with no impact of the final value of color $_{i}$.

For this proof we introduce the notion of the multi-image of a multiset by a function, which extends that of the image of a set by a function. If $M$ is a multiset and $f$ a function defined over $\operatorname{set}(M)$, then $f[M]$ is the multiset defined by ${ }^{3}$ :

$$
\begin{align*}
\operatorname{set}(f[M]) & =f(\operatorname{set}(M)),  \tag{8}\\
\forall y \in \operatorname{set}(f[M]): \mathbf{1}_{f[M]}(y) & =\sum_{x \in f^{-1}(y)} \mathbf{1}_{M}(x) . \tag{9}
\end{align*}
$$

where $f(\operatorname{set}(M))$ is the traditional image ${ }^{4}$ by $f$ of the set $\operatorname{set}(M)$.

This definition implies the following properties:

$$
\begin{align*}
|f[M]| & =|M|,  \tag{10}\\
f[M \otimes m] & =f[M] \otimes m,  \tag{11}\\
f[M] \uplus f[N] & =f[M \uplus N],  \tag{12}\\
f[M] \cup f[N] & \subseteq f[M \cup N] . \tag{13}
\end{align*}
$$

To prove the theorem, we show that the variable color $_{i}$ allocated in each iteration is smaller or equal to $\Delta+\left\lfloor\frac{\Sigma}{\gamma}\right\rfloor$. To this aim we first compute an upper bound of the cardinal of $(\text { neighbors_toks } \cup \text { siblings_toks })_{\mid \mathbb{N}}$, where $M_{\mid S}$ denotes the restriction of the multiset $M$ to the elements of the set $S$.

Let us note $\mathrm{col}_{i}$ the function that associates each process to its coloring at the start of iteration $i$

$$
\begin{align*}
\operatorname{col}_{i}: & \mapsto \\
& \mapsto \mathbb{N} \cup\{\perp\},  \tag{14}\\
p_{j} & \rightarrow \text { color }_{j} .
\end{align*}
$$

Note that by construction, $\operatorname{col}_{i}\left(p_{i}\right)=\perp$.
In the following, we note $\mathcal{S}_{r}^{p}$ the sphere of radius $r$ centered on process $p$ :

$$
\mathcal{S}_{r}^{p}=\{q \in \Pi \mid \operatorname{dist}(p, q)=r\} .
$$

With this definition we have $\mathcal{S}_{0}^{p_{i}}=\left\{p_{i}\right\}, \mathcal{S}_{1}^{p_{i}}=$ neighbors $_{i}$, $\Delta=\max _{p \in \Pi}\left|\mathcal{S}_{1}^{p}\right|$, and $\Sigma=\max _{p \in \Pi}\left|\mathcal{S}_{2}^{p}\right|$. We also define
3. An equivalent and more compact definition could also be $f[M]=$ $\uplus_{x \in M}\left(\{f(x)\} \otimes \mathbf{1}_{M}(x)\right)$.
4. Note that in the general case, for a set $S, f(S) \subseteq f[S]$, i.e. the image of $S$ by $f$ is included in its multi-image by $f$, but $f(S)$ and $f[S]$ are different. $f(S)=f[S]$ only holds for functions that are injective on $S$.
the ball of radius $r$ centered on process $p$ as: $\mathcal{B}_{r}^{p}=\{q \in$ $\Pi \mid \operatorname{dist}(p, q) \leq r\}$.

Using the above definitions and properties, we have

$$
\begin{align*}
\text { neighbors_toks } & =\operatorname{col}_{i}\left(\text { neighbors }_{i}\right) \otimes \gamma,  \tag{15}\\
& \subseteq \operatorname{col}_{i}\left[\text { neighbors }_{i}\right] \otimes \gamma  \tag{16}\\
& \subseteq \operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}}\right] \otimes \gamma  \tag{17}\\
& \subseteq \operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma\right] \tag{18}
\end{align*}
$$

Similarly, we also have

$$
\begin{align*}
& \text { siblings_toks } \\
&=\bigcup_{p_{j} \in \text { neighbors }_{i}} \biguplus_{p_{k} \in \text { neighbors }_{j}} \operatorname{col}_{i}\left[\left\{p_{k}\right\}\right]  \tag{19}\\
&=\bigcup_{p_{j} \in \text { neighbors }_{i}} \operatorname{col}_{i}\left[\biguplus_{p_{k} \in \text { neighbors }_{j}}\left\{p_{k}\right\}\right]  \tag{20}\\
&=\bigcup_{p_{j} \in \text { neighbors }_{i}} \operatorname{col}_{i}\left[\text { neighbors }_{j}\right]  \tag{21}\\
& \subseteq \operatorname{col}_{i}\left[\bigcup_{p_{j} \in \text { neighbors }_{i}} \text { neighbors }_{j}\right]  \tag{22}\\
& \subseteq \operatorname{col}_{i}\left[\mathcal{B}_{2}^{p_{i}}\right] \tag{23}
\end{align*}
$$

Combining (18) and (23) yields:

$$
\begin{align*}
& \text { neighbors_toks } \cup \text { siblings_toks } \\
& \quad \subseteq \operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma\right] \cup \operatorname{col}_{i}\left[\mathcal{B}_{2}^{p_{i}}\right]  \tag{24}\\
& \quad \subseteq \operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{B}_{2}^{p_{i}}\right]  \tag{25}\\
& \quad \subseteq \operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{0}^{p_{i}} \cup \mathcal{S}_{1}^{p_{i}} \cup \mathcal{S}_{2}^{p_{i}}\right] \tag{26}
\end{align*}
$$

Both neighbors_toks and siblings_toks might contain bottom values $(\perp)$, which we need to eliminate to order to reason about the smallest integer remaining in available_toks at line 5 . To this aim, we introduce the restriction of the multiset $X$ to values of $S$, noted $X_{\mid S}$, and defined as

$$
\mathbf{1}_{X_{\mid S}}(x)=\left\{\begin{array}{cl}
\mathbf{1}_{X}(x) & \text { if } x \in S \\
0 & \text { if } x \notin S
\end{array}\right.
$$

Let us note the following two properties of multisets, where $M$ and $N$ are multisets, $m$ and $n$ are positive integers, and $S$ is a set:

$$
\begin{align*}
& M \otimes m \cup M \otimes n=M \otimes \max (m, n),  \tag{27}\\
& f[N] \cap S=\emptyset \Rightarrow f[M]_{\mid S} \subseteq f[M \backslash N] . \tag{28}
\end{align*}
$$

Applying the above two properties to (26) yields:

$$
\begin{align*}
& (\text { neighbors_toks } \cup \text { siblings_toks })_{\mid \mathbb{N}} \\
& \quad \subseteq\left(\operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{1}^{p_{i}} \cup \mathcal{S}_{2}^{p_{i}} \cup \mathcal{S}_{0}^{p_{i}}\right]\right)_{\mid \mathbb{N}}  \tag{29}\\
& \quad \subseteq\left(\operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{2}^{p_{i}} \cup \mathcal{S}_{0}^{p_{i}}\right]\right)_{\mid \mathbb{N}}  \tag{30}\\
& \quad \subseteq\left(\operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{2}^{p_{i}}\right]\right)_{\mid \mathbb{N}} \tag{31}
\end{align*}
$$

Taking the cardinal we have

$$
\begin{align*}
& \mid(\text { neighbors_toks } \cup \text { siblings_toks })_{\mid \mathbb{N}} \mid \\
& \leq\left|\left(\operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{2}^{p_{i}}\right]\right)_{\mid \mathbb{N}}\right|,  \tag{32}\\
& \leq\left|\operatorname{col}_{i}\left[\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{2}^{p_{i}}\right]\right| \text {, }  \tag{33}\\
& \leq\left|\mathcal{S}_{1}^{p_{i}} \otimes \gamma \cup \mathcal{S}_{2}^{p_{i}}\right|,  \tag{34}\\
& \leq\left|\mathcal{S}_{1}^{p_{i}} \otimes \gamma\right|+\left|\mathcal{S}_{2}^{p_{i}}\right|,  \tag{35}\\
& \leq \Delta \times \gamma+\Sigma \text {. } \tag{36}
\end{align*}
$$

color $_{i}$ at line 5 is computed in such a way that

$$
\begin{equation*}
\forall k<\text { color }_{i}: \mathbf{1}_{\text {available_toks }}(k)=0 \tag{37}
\end{equation*}
$$

hence,

$$
\begin{equation*}
\forall k<\text { color }_{i}: \mathbf{1}_{\text {neighbors_toks } \cup \text { siblings_toks }}(k) \geq \gamma, \tag{38}
\end{equation*}
$$

from which we derive,

$$
\begin{equation*}
\mid(\text { neighbors_toks } \cup \text { siblings_toks })_{\mid \mathbb{N}} \mid \geq \gamma \times \text { color }_{i} \tag{39}
\end{equation*}
$$

and so with (36)

$$
\begin{align*}
\gamma \times \text { color }_{i} & \leq \Delta \times \gamma+\Sigma  \tag{40}\\
\operatorname{color}_{i} & \leq \Delta+\frac{\Sigma}{\gamma}  \tag{41}\\
\operatorname{color}_{i} & \leq \Delta+\left\lfloor\frac{\Sigma}{\gamma}\right\rfloor \tag{42}
\end{align*}
$$

This shows that the algorithm allocates only colors in the range $\left[0, \ldots, \Delta+\left\lfloor\frac{\Sigma}{\gamma}\right\rfloor\right\rfloor$, which concludes the proof of the theorem.
$\square_{\text {Theorem } 2}$
The bound of Theorem 2 is realized by the complete graph (in which $\Sigma=0$ ), but is in general not tight, as the results we present for trees later on demonstrate (Algorithm 2 and Theorem 4 in Section 6 and 7). Algorithm 1 can also serve as the basis for a naive sequential (and hence C2-free) distributed coloring procedure, that would propagate the state of the entire graph coloring from process to process, incurring messages with $O(n)$ length, and executing in $O(n)$ steps.

The subsequent contributions of this paper show that a C2-free parallel solution exists for trees that uses: (i) messages of length at most $O(\Delta)$; (ii) $O\left(d\left\lceil\frac{\Delta}{\gamma}\right\rceil\right)$ steps; and (iii) an optimal number of colors. An open problem remains however whether $\mathrm{F} 3 \mathrm{C}(n, \gamma, K, 1)$ can be solved deterministically with a parallel algorithm in an arbitrary graph in a system that suffers conflicts and $\gamma$-collisions.

### 5.3 A necessary and sufficient condition for F3C

Let $\operatorname{F3C}\left(n, \gamma,\left\lceil\frac{\Delta}{\gamma}\right\rceil+1,>1\right)$ denote the problem F3C $\left(n, \gamma,\left\lceil\frac{\Delta}{\gamma}\right\rceil+1, \geq 1\right)$ where at least one process obtains more than one color.
Theorem 3. $\mathrm{F} 3 \mathrm{C}\left(n, \gamma,\left\lceil\frac{\Delta}{\gamma}\right\rceil+1,>1\right)$ can be solved on a tree of maximal degree $\Delta$, iff
$\exists i:\left\lceil\frac{\Delta}{\gamma}\right\rceil>\max \left(\left\{\left\lceil\frac{\Delta_{i}}{\gamma}\right\rceil\right\} \cup\left\{\left.\left\lfloor\frac{\Delta_{j}}{\gamma}\right\rfloor \right\rvert\, p_{j} \in\right.\right.$ neighbors $\left.\left._{i}\right\}\right)$.
To not overload the presentation the formal proof of this theorem is given in the Appendix.

## 6 Solving F3C( $n, \gamma, K, \geq 1$ ) in A Tree

The algorithm presented in this section uses as a skeleton a parallel traversal of a tree [24]. Such a traversal is implemented by control messages that visit all the processes, followed by a control flow that returns to the process that launched the tree traversal.

As claimed previously, Algorithm 2 is a $K$-optimal, parallel, $\mathrm{C} 2 \gamma$-free algorithm that solves $\operatorname{F3C}\left(n, \gamma,\left\lceil\frac{\Delta}{\gamma}\right\rceil+1, \geq 1\right)$ using messages of length at most $O(\Delta)$ in $O\left(d\left\lceil\frac{\Delta}{\gamma}\right\rceil\right)$ steps.

It assumes that a single process initially receives an external message START(), which dynamically defines it as the root of the tree. This message and the fact that processes at distance smaller or equal to 2 do not have the same identity provide the initial asymmetry from which a deterministic coloring algorithm can be built. The reception of the message START() causes the receiving process (say $p_{r}$ ) to simulate the reception of a fictitious message $\operatorname{COLOR}()$, which initiates the sequential traversal.

### 6.1 Messages

The algorithm uses two types of message, denoted COLOR() and TERM().

- The messages COLOR() implement a control flow visiting in parallel the processes of the tree from the root to the leaves. Each of them carries three values, denoted sender, cl_map, and max_cl.
- sender is the identity of the sender of the message. If it is the first message $\operatorname{COLOR}()$ received by a process $p_{i}$, sender defines the parent of $p_{i}$ in the tree.
- cl_map is a dictionary data structure with one entry for each element in neighbors ${ }_{x} \cup\left\{i d_{x}\right\}$, where $p_{x}$ is the sender of the message $\operatorname{COLOR}() . c l \_m a p\left[i d_{x}\right]$ is the set of colors currently assigned to the sender and, for each $i d_{j} \in$ neighbor ${ }_{x}, c l \_m a p\left[i d_{j}\right]$ is the set of colors that $p_{x}$ proposes for $p_{j}$.
- max_cl is an integer defining the color domain used by the sender, namely the color set $\{0,1, \ldots,($ max_cl -1$)\}$. Each child $p_{i}$ of the message sender will use the color domain defined by $\max \left(\max \_c l, \sigma_{i}\right)$ to propose colors to its own children ( $\sigma_{i}$ is defined below). Moreover, all the children of the sender will use the same slot span $\{0,1, \ldots,($ max_cl -1$)\}$ to schedule their message broadcasts. This ensures that their message broadcasts will be collision-free ${ }^{5}$.
- The messages TERM () propagate the return of the control flow from the leaves to the root. Each message TERM () carries two values: the identity of the destination process (as this message is broadcast, this allows any receiver to know whether it should process this message), and the identity of the sender.

### 6.2 Local variables

Each process $p_{i}$ manages the following local variables. The constant $\Delta_{i}=\mid$ neighbors $_{i} \mid$ is the degree of $p_{i}$, while the constant $\sigma_{i}=\left\lceil\frac{\Delta_{i}}{\gamma}\right\rceil+1$ is the number of colors needed to color the star graph made up of $p_{i}$ and its neighbors.

- state $_{i}$ (initialized to 0 ) is used by $p_{i}$ to manage the progress of the tree traversal. Each process traverses five different states during the execution of the algorithm. States 1 and 3 are active states: a process in state 1 broadcasts a $\operatorname{COLOR}()$ message to its neighbors, while a process in state 3 broadcasts a message TERM() which has a meaning only for its parent. States 0 and 2 are

[^1]waiting states in which a process listens on the broadcast channels but cannot send any message. Finally, state 4 identifies local termination.

- parent $t_{i}$ stores the identity of the process $p_{j}$ from which $p_{i}$ receives a message $\operatorname{COLOR}()$ for the first time (hence $p_{j}$ is the parent of $p_{i}$ in the tree). The root $p_{r}$ of the tree, defined by the reception of the external message $\operatorname{START}()$, is the only process such that parent $t_{r}=i d_{r}$.
- colored $_{i}$ is a set containing the identities of the neighbors of $p_{i}$ that have been colored.
- to_color $i_{i}$ is the set of neighbors to which $p_{i}$ must propagate the coloring (network traversal).
- color_map $\operatorname{man}_{i}\left[\right.$ neighbors $\left.i_{i} \cup\left\{i d_{i}\right\}\right]$ is a dictionary data structure where $p_{i}$ stores colors of its neighbors in color_map ${ }_{i}\left[\right.$ neighbors $\left._{i}\right]$, and its own colors in color_map ${ }_{i}\left[i d_{i}\right] ;$ colors $_{i}$ is used as a synonym of color_map ${ }_{i}\left[i d_{i}\right]$.
- $m a x_{-} c l_{i}$ defines both the color domain from which $p_{i}$ can color its children, and the time slots (rounds) at which its children will be allowed to broadcast.
- slot_spani is set to the value max_cl carried by the message COLOR() received by $p_{i}$ from its parent. As this value is the same for all the children of its parent, they will use the same slot span to define the slots during which each child will be allowed to broadcast messages.

### 6.3 Initial state

In its initial state (state $=0$ ), a process $p_{i}$ waits for a message $\operatorname{COLOR}()$. As said previously, a single process receives the external message START(), which defines it at the root process. It is assumed that $C L O C K=0$ when a process receives this message. When this happens, the corresponding process $p_{i}$ simulates the reception of the message COLOR $\left(i d_{i}, c l \_m a p, \sigma_{i}\right)$ where $c l \_m a p\left[i d_{i}\right]$ defines its color, namely, $(C L O C K+1) \bmod \sigma_{i}$ (lines 2-4). As a result, at round number 1 , the root broadcasts a message $\operatorname{COLOR}()$ to its children (line 33).

### 6.4 Algorithm: reception of a message $\operatorname{COLOR}()$

When a process $p_{i}$ receives a message $\operatorname{COLOR}()$ for the first time, it is visited by the network traversal, and must consequently (a) obtain an initial color set, and (b) propagate the network traversal, if it has children. The processing by $p_{i}$ of this first message COLOR(sender, cl_map, max_cl) is done at lines 7-29. First, $p_{i}$ saves the identity of its parent (the sender of the message) and its proposed color set (lines 7-8), initializes colored $_{i}$ to $\{$ sender $\}$, and to_color $_{i}$ to its other neighbors (lines 9-10). Then $p_{i}$ obtains a color set proposal from the dictionary $c l \_m a p$ carried by the message (line 11), computes the value max_cl $_{i}$ from which its color palette will be defined, and saves the value max_cl carried by the message $\operatorname{COLOR}()$ in the local variable slot_span ${ }_{i}$ (line 12). Let us remind that the value $\max _{-} c l_{i}$ allows $p_{i}$ to know the color domain used up to now, and the rounds at which it will be able to broadcast messages (during the execution of the algorithm) in a collision-free way.

Then, the behavior of $p_{i}$ depends on the value of to_color $i_{i}$. If to_color $r_{i}$ is empty, $p_{i}$ is a leaf, and there is no more process to color from it. In this case, $p_{i}$ proceeds to state 3 (line 29).

```
1 Init: \(\sigma_{i}=\left\lceil\frac{\Delta_{i}}{\gamma}\right\rceil+1\); state \(_{i} \leftarrow 0\); colors \(_{i} \leftarrow \emptyset\); colors \(_{i}\) stands for
    color_map \({ }_{i}\left[i d_{i}\right]\).
2 when \(\operatorname{START}()\) is received do \(\triangle A\) single proc. receives this message.
    \(p_{i}\) executes lines 6-30 as if it received
    \(\operatorname{COLOR}\left(i d_{i}, c l \_m a p, \sigma_{i}\right)\)
            where \(c l \_\operatorname{map}\left[i d_{i}\right]=\left\{(C L O C K+1) \bmod \sigma_{i}\right\}\).
5 when COLOR(sender, \(\left.c l \_m a p, m a x \_c l\right)\) is received do
    if first message \(\operatorname{COLOR}()\) received then
        parent \(_{i} \leftarrow\) sender;
        color_map \({ }_{i}\left[\right.\) parent \(\left._{i}\right] \leftarrow\) cl_map \([\) sender \(] ;\)

            \({\text { bcast TERM }\left(\text { parent }_{i}, i d_{i}\right) ; \text { state }_{i} \leftarrow 4 .}^{\leftarrow}\).
    when \(\operatorname{TERM}(\) dest,\(i d)\) is received do
        if \(\left(\right.\) dest \(\left.\neq i d_{i}\right)\) then discard the message (skip lines 38-41);
        colored \(_{i} \leftarrow\) colored \(_{i} \cup\{i d\}\);
        if colored \(_{i}=\) neighbors \(_{i}\) then
            if parent \(_{i}=i d_{i}\) then the root \(p_{i}\) claims termination;
            else state \(_{i} \leftarrow 3\).
    Algorithm 2: $\mathrm{C} 2 \gamma$-free algorithm solving $\operatorname{CCMC}\left(n, \gamma,\left\lceil\frac{\Delta}{\gamma}\right\rceil+1, \geq\right.$ 1) in tree networks (code for $p_{i}$ )

If to_color $i_{i}$ is not empty, $p_{i}$ has children. It has consequently to propose a set of colors for each of them, and save these proposals in its local dictionary color_map ${ }_{i}\left[\right.$ neighbors $\left._{i}\right]$. To this end, $p_{i}$ computes first the domain of colors it can use, namely, the set $\left\{0,1, \ldots,\left(\max _{\_} c l_{i}-1\right)\right\}$, and considers that each of these colors $c$ is represented by $\gamma$ tokens colored $c$. Then, it computes the multiset, denoted tokens $_{i}$, containing all the
colored tokens it can use to build a color set proposal for each of its children (line 14). The multiset tokens $i_{i}$ is initially made up of all possible colored tokens, from which are suppressed (a) all tokens associated with the colors of $p_{i}$ itself, and, (b) one colored token for each color in color_map $_{i}\left[\right.$ parent $\left._{i}\right]$ (this is because, from a coloring point of view, its parent was allocated one such colored token for each of its colors).

Then, $p_{i}$ checks if it has enough colored tokens to allocate at least one colored token to each of its children (assigning thereby the color of the token to the corresponding child). If the predicate $\mid$ tokens $_{i}|\geq|$ to_color $_{i} \mid$ is satisfied, $p_{i}$ has enough colored tokens and can proceed to assign set of colors to each of its children (lines 25-27). Differently, if the predicate $\mid$ tokens $_{i}|<|$ to_color $_{i} \mid$ is satisfied, $p_{i}$ has more children than available colored tokens. It must therefore find more colored tokens. To do that, if colors ${ }_{i}$ (i.e., color_map $\left.{ }_{i}\left[i d_{i}\right]\right)$ has more than one color, $p_{i}$ suppresses one color from colors $_{i}$, adds the $\gamma$ associated colored tokens to the multiset tokens $_{i}$ (lines 16-18), and re-enters the "while" loop (line 15). If colors $_{i}$ has a single color, this color cannot be suppressed from colors $_{i}$. In this case, $p_{i}$ considers the color set of its parent (color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ ), takes the maximal color of this set, suppresses it from color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$, adds the associated colored token to the multiset tokens ${ }_{i}$ (lines 19-24), and-as before-re-enters the "while" loop (line 15). Only one token colored $c l$ is available because the $(\gamma-1)$ other tokens colored $c l$ were already added into the multiset tokens $i$ during its initialization at line 14.

As already said, when the predicate $\mid$ tokens $_{i} \mid<$ $\mid t_{0}$ color ${ }_{i} \mid$ (line 15) becomes false, tokens $i_{i}$ contains enough colored tokens to assign to $p_{i}$ 's children. This assignment is done at lines 25-27. Let $c h=\mid t_{0}$ color $_{i} \mid$ (number of children of $p_{i}$ ); $p_{i}$ extracts $c h$ pairwise disjoint and nonempty subsets of the multiset tokens ${ }_{i}$, and assigns each of them to a different neighbor. "Non-empty non-intersecting multisets" used at line 25 means that, if each of $z$ multisets $t k\left[i d_{x}\right]$ contains a token with the same color, this colored token appears at least $z$ times in the multiset tokens $i_{i}$.

If the message COLOR (sender, cl_map, - ) received by $p_{i}$ is not the first one, it was sent by one of its children. In this case, $p_{i}$ keeps in its color set color_mapi $\left[i_{i}\right]$ ( colors $_{i}$ ) only the colors allowed by its child sender (line 30). Hence, when $p_{i}$ has received a message $\operatorname{COLOR}()$ from each of its children, its color set colors $_{i}$ has its final value.

### 6.5 Algorithm: broadcast of a message

A process $p_{i}$ is allowed to broadcast a message only at the rounds corresponding to a color it obtained (a color in colors $_{i}=$ color_map $_{i}\left[i d_{i}\right]$ computed at lines 11, 17, and 30), provided that its current local state is 1 or 3 (line 31).

If state $_{i}=1, p_{i}$ received previously a message $\operatorname{COLOR}()$, which entailed its initial coloring and a proposal to color its children (lines 13-28). In this case, $p_{i}$ propagates the tree traversal by broadcasting a message COLOR() (line 33), which will provide each of its children with a coloring proposal. Process $p_{i}$ then progresses to the local waiting state 2.

If state $=3$, the coloring of the tree rooted at $p_{i}$ is terminated. Process $p_{i}$ consequently broadcasts the message $\operatorname{TERM}\left(\right.$ parent $\left._{i}, i d_{i}\right)$ to inform its parent of it. It also progresses from state 3 to state 4 , which indicates its local termination (line 35).

### 6.6 Algorithm: reception of a message TERM()

When a process $p_{i}$ receives such a message it discards it if it is not the intended destination (line 37). If the message is for it, $p_{i}$ adds the sender's identity to the set colored $_{i}$ (line 38). Finally, if colored $_{i}=$ neighbors $_{i}, p_{i}$ learns that the subtree rooted at it is colored (line 39). It follows that, if $p_{i}$ is the root parent $_{i}=i$ ), it learns that the algorithm terminated. Otherwise, it enters state 3, that will direct it to report to its parent the termination of the coloring of its underlying subtree.

### 6.7 Solving $\operatorname{F3C}(n, \gamma, K, 1)$ in a tree

Algorithm 2 can be easily modified to solve F3C $(n, \gamma, K, 1)$. When a process enters state 3 (at line 29 or line 41), it reduces color_map $_{i}\left[i d_{i}\right]$ (i.e., colors $_{i}$ ) to obtain a singleton.

## 7 F3C( $n, \gamma, K, \geq 1$ ) IN A Tree: Cost and Proof

The proof assumes $n>1$. Let us remember that colors $_{i}$ and color_map ${ }_{i}\left[i d_{i}\right]$ are the same local variable of $p_{i}$, and $p_{r}$ denotes the dynamically defined root process.

### 7.1 Cost of the algorithm

Each non-leaf process broadcasts one message $\operatorname{COLOR}()$, and each non-root process broadcasts one message TERM(). Let $x$ be the number of leaves. There are consequently $(2 n-(x+$ 1)) broadcasts. As $\Delta \leq x+1^{(6)}$, the number of broadcast is upper bounded by $2 n-\Delta$.
$\operatorname{TERM}()$ messages are of fixed length, while COLOR() message carry some fixed-length information, and the dictionary color_map $i_{i}$, which contains $\Delta_{i}+1$ entries. As a result, the length of messages is bounded by $O(\Delta)$.

Given an execution whose dynamically defined root is the process $p_{r}$, let $d$ be the height of the corresponding tree. A recursive analysis of message patterns yields a time complexity of $O\left(d\left\lceil\frac{\Delta}{\gamma}\right\rceil\right)$.

### 7.2 Proof of the algorithm

The proof is decomposed into lemmas showing that the algorithm (a) is itself conflict-free and $\gamma$-collision-free, (b) terminates, and (c) associates with each process $p_{i}$ a non-empty set colors $_{i}$ satisfying the Conflict-freedom, $\gamma$-Collisionfreedom and Efficiency properties defined in Section 4. To this end, a notion of well-formedness suited to $\operatorname{COLOR}()$ messages is introduced.

## Lemma 1. Algorithm 2 is conflict-free.

[^2]Proof The algorithm uses two types of message: COLOR() and TERM(). We first show conflict-freedom for COLOR() messages (if a process broadcasts a message $\operatorname{COLOR}()$, none of its neighbors is broadcasting any message in the same round). Let us first notice that a process $p_{i}$ broadcasts at most one message $\operatorname{COLOR}()$, and one message $\operatorname{TERM}()$ (this is due to the guard state $i \in\{1,3\}$, line 31 , and the fact that the broadcast of a message makes its sender progress to the waiting state 2 or 4 ). Moreover, let us make the following observations.

- Observation 1: The first message sent by any process is of type COLOR () (line 33).
- Observation 2: Except for the root process, a message COLOR() is always broadcast by a process after it received a message $\operatorname{COLOR}()$ (which triggers the execution of lines 5-30).
- Observation 3: Except for leaf processes, a message $\operatorname{TERM}()$ is always broadcast by a process after it received a message $\operatorname{TERM}()$ from each of its children (lines 36-41 and line 34).
Observations 1 and 2 imply that when the root process broadcasts its COLOR () message, none of its neighbors is broadcasting a message, and they all receive the root's COLOR() message without conflict. Let us now consider a process $p_{i}$, different from the root, which receives its first message $\mathrm{COLOR}_{k}()$ (from its parent $p_{k}$ ). Because there is no cycle in the communication graph (a tree), all the children of $p_{i}$ (neighbors ${ }_{i} \backslash\left\{p_{k}\right\}$ ) are in state 0 , waiting for their $\operatorname{COLOR}()$ message. Moreover, due to Observations 1 and 2, they will receive from $p_{i}$ their message $\operatorname{COLOR}()$ without conflict. After sending its COLOR() message, $p_{i}$ 's parent $p_{k}$ remains in the waiting state 2 until it receives a TERM() message from all its children (lines 38-39), which include $p_{i}$. As a consequence, $p_{k}$ is not broadcasting any message in the round in which it receives $p_{i}{ }^{\prime}$ 's COLOR () message, which is consequently received without conflict by all its neighbors.

As far the messages $\operatorname{TERM}()$ are concerned we have the following. Initially, only a leaf process can broadcast a message, and when it does it, its parent is in the waiting state 2 (since it broadcasts a message $\operatorname{COLOR}()$ at line 33 and it must receive messages $\operatorname{TERM}()$ to proceed to state 3). Hence, a message $\operatorname{TERM}()$ broadcast by a leaf cannot entail conflict. Let us now consider a non-leaf process $p_{i}$. It follows from Observation 3 that $p_{i}$ can broadcast a message $\operatorname{TERM}()$ only when its children are in state 4 (in which they cannot broadcast), and its parent (because it has not yet received a message TERM() from each of its children) is in the waiting state 2 . Hence, we conclude that the broadcast of a message TERM() by a non-leaf process is conflict-free, which concludes the proof of the lemma.
$\square_{\text {Lemma } 1}$
Definition A message COLOR(sender, cl_map,max_cl) is well formed if its content satisfies the following properties. Let sender $=i d_{i}$.
M1 The keys of the dictionary data structure cl_map are the identities in neighbors $s_{i} \cup\left\{i d_{i}\right\}$.
M2 $\forall i d \in\left(\right.$ neighbors $\left._{i} \cup\left\{i d_{i}\right\}\right): c l \_\operatorname{map}[i d] \neq \emptyset$.
M3 $\forall i d \in$ neighbors $_{i}: c l \_m a p[i d] \cap c l \_m a p\left[i d_{i}\right]=\emptyset$.
M4 $\forall c: \mid\left\{i d_{j} \in\right.$ neighbors $\left._{i}: c \in c l_{-} \operatorname{map}\left[i d_{j}\right]\right\} \mid \leq \gamma$.
M5 $1<$ max_cl $\left\lceil\left\lceil\frac{\Delta}{\gamma}\right\rceil+1\right.$.
M6 $\forall i d \in\left(\right.$ neighbors $\left._{i} \cup\left\{i d_{i}\right\}\right): 0 \leq c l \_m a p[i d]<\max _{-} c l$.

Once established in Lemma 3, not all properties M1M6 will be explicitly used in the lemmas that follow. They are used by induction to proceed from one well-formed message to another one.

Lemma 2. If a message COLOR(sender, cl_map, max_cl) received by a process $p_{i} \neq p_{r}$ is well formed and entails the execution of lines 7-29, the while loop (lines 15-24) terminates, and,
 are not empty, and their intersection is empty.
Proof Let us consider a process $p_{i} \neq p_{r}$ that receives a wellformed $\operatorname{COLOR}_{j}\left(\right.$ sender, $\left.c l \_m a p, \max \_c l\right)$ message from $p_{j}$. Let us assume $\operatorname{COLOR}()$ causes $p_{i}$ to start executing the lines 7-29, i.e., $\operatorname{COLOR}()$ is the first such message received by $p_{i}$. The body of the while loop contains two lines (lines 17 and 23) that select elements from two sets, colors $_{i}$ and color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ respectively.

Before discussing the termination of the while loop, we show that lines 17 and 23 are well defined, i.e. the sets from which the elements are selected are non-empty. To this aim, we prove by induction that the following invariant holds in each iteration of the loop:

$$
\begin{gather*}
\text { color_map }_{i}\left[\text { parent }_{i}\right] \neq \emptyset,  \tag{43}\\
\text { colors }_{i} \neq \emptyset,  \tag{44}\\
\mid \text { tokens }_{i}\left|=\begin{array}{l}
\gamma \times \max _{2} \text { cl } \\
i
\end{array}-\gamma \times\right| \text { colors }_{i} \mid- \\
\mid \text { color_mapi }_{i}\left[\text { parent }_{i}\right] \mid . \tag{45}
\end{gather*}
$$

Just before the loop (i.e., before line 15), Assertion (43) follows from the assignment to color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ at line 8 and the property M 2 of $\operatorname{COLOR}_{j}()\left(i d_{j}=\right.$ parent $\left._{i}\right)$. Assertion (44) also follows from M2 (colors $i_{i}$ is synonym of color_map $i_{i}\left[i d_{i}\right]$ ). Assertion (45) follows from M3, M6, and the initialization of $\max _{-} c l_{i}$ at line 12.

Let us now assume that Assertion (43) holds at the start of a loop iteration (i.e., just before lines 16). There are two cases.

- If $\mid$ colors $_{i} \mid>1$, lines $19-24$ are not executed, and consequently color_map m $_{i}$ parent $\left._{i}\right]$ is not modified. It follows from the induction assumption that Assertion (43) still holds.
- If $\mid$ colors $_{i} \mid \leq 1$, we have the following. Because we are in the while loop, we have $\mid$ tokens $_{i}|<|$ to_colors $_{i} \mid$, which, combined with Assertion (45), implies

$$
\begin{aligned}
\mid \text { to_colors }_{i} \mid> & \gamma \times \text { max_cl }_{i}-\gamma \times \mid \text { colors }_{i} \mid \\
& -\mid \text { color_map }_{i}\left[\text { parent }_{i}\right] \mid,
\end{aligned}
$$

from which we derive

$$
\begin{aligned}
& \mid \text { color_map }_{i}\left[\text { parent }_{i}\right] \mid \\
& \quad>\gamma \times \text { max_cl }_{i}-\gamma \times \mid \text { colors }_{i}|-| \text { to_colors }_{i} \mid, \\
& \quad>\gamma \times \text { max_cl }_{i}-\gamma \times \mid \text { colors }_{i} \mid-\left(\Delta_{i}-1\right) \\
& \quad>\gamma \times \sigma_{i}-\gamma \times \mid \text { colors }_{i} \mid-\left(\Delta_{i}-1\right), \\
& \quad>\gamma \times\left(\left\lceil\frac{\Delta_{i}}{\gamma}\right\rceil+1\right)-\gamma \times \mid \text { colors }_{i} \mid-\left(\Delta_{i}-1\right) \\
& \quad>\Delta_{i}+\gamma-\gamma \times \mid \text { colors }_{i} \mid-\left(\Delta_{i}-1\right) \\
& \quad>\gamma \times\left(1-\mid \text { colors }_{i} \mid\right)+1
\end{aligned}
$$

Hence, because $\mid$ colors $_{i} \mid \leq 1$, we obtain $\mid$ color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right] \mid>1$, which means that $p_{i}{ }^{\prime} \mathrm{s}$ local variable color_map m $_{i}$ parent $\left._{i}\right]$ contains at least two elements before the execution of line 16. Because only one color is removed from color_map parent $\left._{i}\right]$,
this local variable remains non-empty after lines 23-24, thus proving Assertion (43).
Let us now assume that both Assertion (44) and Assertion (45) hold at the start of a loop iteration (i.e., just before line 16). There are two cases.

- Case $\mid$ colors $_{i} \mid>1$. In this case we have: (i) one color is removed from colors $_{i}$, (ii) $\gamma$ colored tokens are added to tokens ${ }_{i}$, and (iii) color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ remains unchanged. $\mid$ colors $_{i} \mid>1$ and (i) imply that Assertion (44) remains true; and (i) and (ii) mean that Assertion (45) is preserved.
- Case $\mid$ colors $_{i} \mid \leq 1$. In this case we have: (i) one color is removed from color_mapi $\left[\right.$ parent $\left.i_{i}\right]$, and one colored token added to tokens ${ }_{i}$, and (ii) colors ${ }_{i}$ stays unchanged. (i) implies that Assertion (45) remains true, and (ii) ensures Assertion (44) by assumption.
This concludes the proof that the three assertions (43)-(45) are a loop invariant. Hence, Assertion (43) and Assertion (44) imply that lines 17 and 23 are well defined.

Let us now observe that, in each iteration of the loop, new colored tokens are added to tokens ${ }_{i}$, and thus $\mid$ tokens $_{i} \mid$ is strictly increasing. Because $\mid$ to_color $_{i} \mid$ remains unchanged, the condition $\mid$ tokens $_{i}|<|$ to_color $_{i} \mid$ necessarily becomes false at some point, which proves that the loop terminates.

Just after the loop, the invariant is still true. In particular Assertion (43) and Assertion (44) show that both the sets colors $_{i}$ and color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ are not empty when $p_{i}$ exits the while loop.

Finally, due to the fact that the message $\operatorname{CoLOR}_{j}()$ is well formed, it follows from M3 that we have colors $_{i} \cap$ color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]=\emptyset$ after line 11. As colors are added neither to colors $_{i}$, nor to color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ in the loop, their intersection remains empty, which concludes the proof of the lemma.
$\square_{\text {Lemma } 2}$

Lemma 3. All messages COLOR() broadcast at line 33 are well formed.
Proof To broadcast a message $\operatorname{COLOR}()$, a process $p_{i}$ must be in local state 1 (line 33). This means that $p_{i}$ executed line 28 , and consequently previously received a message COLOR (sender, cl_map, max_cl) that caused $p_{i}$ to execute lines 7-29.

Let us first assume that $\operatorname{COLOR}()$ is well formed. It then follows from Lemma 2 that $p_{i}$ exits the while loop, and each of colors $_{i}$ and color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ is not empty (A), and they have an empty intersection (B). When considering the message $\operatorname{COLOR}\left(i d_{i}\right.$, color_map $_{i}$, max_ $\left._{-} l_{i}\right)$ broadcast by $p_{i}$ we have the following.

- M1 follows from the fact that the entries of the dictionary data structure created by $p_{i}$ are: color_map $_{i}\left[\right.$ parent $\left._{i}\right]$ (line 8 ), color_map ${ }_{i}\left[i d_{i}\right]$ (line 11), and color_map ${ }_{i}[i d]$ for each $i d \in$ to_colors $_{i}=$ neighbors $_{i} \backslash\left\{\right.$ parent $\left._{i}\right\}$ (lines 10 and 27), and the observation that no entry is ever removed from color_map ${ }_{i}$ is the rest of the code.
- M2 follows from (A) for color_mapi $\left[\right.$ parent $\left._{i}\right]$ and color_map ${ }_{i}\left[i d_{i}\right]$, from line 25 for the identities in to_colors $_{i}=$ neighbors $_{i} \backslash\left\{\right.$ parent $\left._{i}\right\}$ (due to $\mid$ tokens $_{i} \mid \geq$
$\mid$ to_colors $_{i} \mid$ when line 25 is executed, and the nonintersection requirement of the $t k[i d]$ sets, no $t k[i d]$ is empty), and from the observation that color_map $i_{i}$ is not modified between the end of line 27 and the broadcast of line 33. This last claim is derived from the fact that color_map m is only modified when messages are $^{\text {in }}$ wher received, and that neither $p_{i}$ 's parent nor $p_{i}{ }^{\prime} s$ children are in states that allow them to send messages while $p_{i}$ is transitioning from line 27 to line 33.
- Similarly, M3 follows
- for $i d=$ parent $_{i}$ : from (B) and the fact that color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right]$ never increases,
- for $i \bar{d} \in$ to_color $_{i}=$ neighbors $_{i} \backslash\left\{\right.$ parent $\left._{i}\right\}$ : from the fact that, due to lines 14 and 17, at line 25 tokens $_{i}$ contains no token whose color belongs to colors $_{i}$, from which we have $t k[i d] \cap$ color_map $_{i}\left[i d_{i}\right]=\emptyset$ for any $i d \in$ to_color $_{i}$.
- M4 follows from the construction of tokens $i_{i}$. This construction ensures that, for any color $c$, tokens $_{i}$ contains at most $\gamma$ tokens with color $c$ (lines 14,18 , and 22).
- M5 is an immediate consequence of the assignment $m a x_{n} c l_{i} \leftarrow \max \left(\max _{-} c l, \sigma_{i}\right)$ at line 12.
- M6 follows from the following observations:
- for $i d \in\left\{i d_{i}\right.$, parent $\left._{i}\right\}$ : from max_cl $\leq$ max_cl $_{i}$ (line 12) and the fact that the message COLOR() received by $p_{i}$ is well formed (hence color_map $i_{i}\left[i d_{i}\right] \cup$ color_map ${ }_{i}\left[\right.$ parent $\left._{i}\right] \subseteq[0, \ldots,($ max_cl -1$\left.)]\right)$,
- for $i d \in$ to_color $_{i}=$ neighbors $_{i} \backslash\left\{\right.$ parent $\left._{i}\right\}$ : from the fact that tokens $i_{i}$ contains only tokens whose color is in $\left[0, \ldots,\left(\right.\right.$ max_cl $\left.\left._{i}-1\right)\right]$ (line 14).
The previous reasoning showed that, if a process receives a well formed message $\operatorname{COLOR}()$, executes lines 7-29 and line 33 , the message $\operatorname{COLOR}\left(i d_{i}\right.$, color_map $_{i}$, max_cl $\left._{i}\right)$ it will broadcast at this line is well formed. Hence, to show that all messages broadcast at line 33 are well formed, it only remains to show that the message COLOR $\left(i d_{r}\right.$, color_map $_{r}$, max_c $\left._{-} l_{r}\right)$ broadcast by the root $p_{r}$ is well formed. Let us remember that neighbors ${ }_{r}$ is a constant defined by the structure of the tree, and parent ${ }_{r}=$ $i d_{r} \notin$ neighbors ${ }_{r}$.

Let us notice that COLOR (id, cl_map, max_cl) sent by $p_{r}$ to itself at line 4 is not well formed. This is because, $c l \_m a p[i d]$ is not defined for $i d \in$ neighbors $_{i}$. When $p_{r}$ receives this message we have the following after line 14:
$\mid$ tokens $_{r} \left\lvert\,=\gamma \times \sigma_{r}-\gamma=\gamma \times\left(\sigma_{r}-1\right)=\gamma\left\lceil\frac{\Delta_{r}}{\gamma}\right\rceil \geq \Delta_{r}\right.$, from which we conclude $\mid$ tokens $_{r}\left|\geq \Delta_{r}=\right|$ to_colors $_{r} \mid=$ $\left|n^{2} i g h b o r s_{i}\right|$. Hence, $p_{r}$ does not execute the loop body, and proceeds to lines $25-27$ where it defines the entries color_map $_{r}[i d]$ for $i d \in$ to_colors $_{r}=$ neighbors $r_{r}$. A reasoning similar to the previous one shows that the message COLOR $\left(i d_{r}\right.$, color_map $_{r}$, max_cl $_{r}$ ) broadcast by $p_{r}$ at line 33 satisfies the properties M1-M6, and is consequently well formed. (The difference with the previous reasoning lies in the definition of the set to_colors $_{i}$ which is equal to neighbors $_{i} \backslash\left\{\right.$ parent $\left._{i}\right\}$ for $p_{i} \neq p_{r}$, and equal to neighbors $r_{r}$ for $p_{r}$.)
$\square_{\text {Lemma } 3}$

Lemma 4. If a process $p_{i}$ computes a color set ( colors $_{i}$ ), this set is not empty.

Proof Let us first observe that, if a process $p_{i} \neq p_{r}$ receives a message COLOR (-, cl_map, -), the previous lemma means that this message is well formed, and due to property M2, its field $c l \_m a p\left[i d_{i}\right]$ is not empty, from which follows that the initial assignment of a value to color_map $\operatorname{man}_{i}\left[d_{i}\right] \equiv$ colors $_{i}$ is a non-empty set. Let us also observe, that, even if it is not well formed the message COLOR $\left(-, c l \_m a p,-\right)$ received by the root satisfies this property. Hence, any process that receives a message $\operatorname{COLOR}()$ assigns first a non-empty value to color_map $_{i}\left[i d_{i}\right] \equiv$ colors $_{i}$.

Subsequently, a color can only be suppressed from color_map $_{i}\left[i d_{i}\right] \equiv$ colors $_{i}$ at line 30 when $p_{i}$ receives a message $\operatorname{COLOR}()$ from one of its children. If $p_{i}$ is a leaf, it has no children, and consequently never executes line 30. So, let us assume that $p_{i}$ is not a leaf and receives a message COLOR $\left(i d_{j}, c l \_m a p,-\right)$ from one of its children $p_{j}$. In this case $p_{i}$ previously broadcast at line 33 a message $\operatorname{COLOR}\left(i d_{i}\right.$, color_map $\left._{i},-\right)$ that was received by $p_{j}$ and this message is well formed (Lemma 3).

A color $c$ that is suppressed at line 30 when $p_{i}$ processes COLOR $\left(i d_{j}, c l \_m a p,-\right)$ is such that $c \in$ colors $_{i}$ and $c \notin c l \_m a p\left[i d_{i}\right] . c l \_m a p\left[i d_{i}\right]$ can be traced back to the local variable color_map ${ }_{j}\left[i d_{i}\right]$ used by $p_{j}$ to broadcast $\operatorname{COLOR}()$ at line 33. Tracing the control flow further back, color_ $\operatorname{map}_{j}\left[i d_{i}\right]$ was initialized by $p_{j}$ to color_map ${ }_{i}\left[i d_{i}\right]$ (line 8 ) when $p_{j}$ received the well-formed message COLOR() from $p_{i}$. When processing the COLOR() message received from $p_{i}$, process $p_{j}$ can suppress colors from color_ $\operatorname{map}_{j}\left[i d_{i}\right]$ only at line 23 , where it suppresses colors starting from the greatest remaining color. We have the following.

- If $p_{i}$ is not the root, the message $\operatorname{COLOR}()$ it received was well formed (Lemma 3). In this case, it follows from the proof of Lemma 2 that it always remains at least one color in color_map ${ }_{j}\left[d_{i}\right]$.
- If $p_{i}=p_{r}$, its set colors $_{r}$ is a singleton (it "received" $\operatorname{COLOR}\left(i d_{r}, c l \_m a p_{r},-\right)$ where $c l \_\operatorname{map}_{r}$ has a single entry, namely $\left.c l_{-} \operatorname{map}_{r}\left[i d_{r}\right]=\{1\}\right)$. When $p_{j}$ computes tokens $_{j}$ (line 14) we have
$\mid$ tokens $_{j} \left\lvert\,=\gamma \times \max \left(\sigma_{r}, \sigma_{j}\right)-\gamma=\gamma\left\lceil\frac{\max \left(\Delta_{r}, \Delta_{j}\right)}{\gamma}\right\rceil \geq\right.$ $\max \left(\Delta_{r}, \Delta_{j}\right) \geq \Delta_{j}=\mid$ to_colors $_{j} \mid$,
from which follows that $\mid$ tokens $_{j}|\geq|$ to_colors $_{j} \mid=$ $\mid$ neighbor $s_{j} \mid-1$. Hence, $p_{j}$ does not execute the loop, and consequently does not modify color_map $\left[i d_{r}\right]$.
Consequently, the smallest color of colors $_{i} \equiv$ color_map ${ }_{i}\left[i d_{i}\right]$ is never withdrawn from color_map $_{j}\left[i d_{i}\right]$. It follows that, at line 30, $p_{i}$ never withdraws its smallest color from the set color_map $\left[i d_{i}\right]$. $\square_{\text {Lemma } 4}$

Lemma 5. If $p_{i}$ and $p_{j}$ are neighbors colors ${ }_{i} \cap$ colors $_{j}=\emptyset$.
Proof As all color sets are initialized to $\emptyset$, the property is initially true. We show that, if a process receives a message $\operatorname{COLOR}()$, the property remains true. As TERM() messages do not modify the coloring (lines 36-41) they do not need to be considered.

Let us consider two neighboring processes $p_{i}$ and $p_{j}$, which compute their color sets (if none or only one of $p_{i}$ and $p_{j}$ computes its color set, the lemma is trivially satisfied). As the network is a tree, one of them is the parent of the other. Let $p_{i}$ be the parent of $p_{j}$.

Process $p_{i}$ broadcasts a message $\operatorname{COLOR}\left(-, c l \_m a p,-\right)$ at line 33 in which the set $c l \_m a p\left[i d_{j}\right]$ is color_map ${ }_{i}\left[i d_{j}\right]$, as computed at line 25 . If this message is received by $p_{j}$, this set will in turn be assigned to color_map ${ }_{i}\left[i d_{j}\right]$ at $p_{j}$. As this message is well formed (Lemma 3), we therefore have color_map $i_{i}\left[i d_{i}\right] \cap$ color_map $_{j}\left[i d_{j}\right]=\emptyset$ (Property M3 of a well-formed message). Then, while $p_{i}$ can be directed to suppress colors from color_map ${ }_{i}\left[i d_{i}\right]$ at line 30 , it never adds a color to this set. The same is true for $p_{j}$ and color_map ${ }_{j}\left[i d_{j}\right]$. It follows that the predicate color_map ${ }_{i}\left[i d_{i}\right] \cap$ color_map ${ }_{j}\left[i d_{j}\right]=\emptyset$ can never be invalidated. $\quad \square_{\text {Lemma } 5}$

Lemma 6. $\forall i, \forall c: \mid\left\{j: j \in\right.$ neighbors $_{i} \wedge c \in$ colors $\left._{j}\right\} \mid \leq \gamma$.
Proof The property is initially true. We show that it remains true when processes receive messages.

Let us consider a process $p_{i}$ that broadcasts a message $\operatorname{COLOR}()$. Due to the fact that such messages are broadcast only at line 33, it follows from Lemma 3 that the message COLOR $\left(i d_{i}, c l \_m a p,-\right)$ broadcast by $p_{i}$ is well formed. Hence, it satisfies property M4. When processing this message
A each child $p_{j}$ of $p_{i}$ adopts $c l \_m a p\left[i d_{j}\right]$ as its initial color set and assigns it to color_map ${ }_{j}\left[i d_{j}\right]$;
B $p_{i}$ 's parent $p_{k}$ uses $c l \_m a p\left[i d_{k}\right]$ to update color_map ${ }_{k}\left[i d_{k}\right]$ at line 30 such that color_map ${ }_{k}\left[i d_{k}\right]$ $\subseteq c l_{-} \operatorname{map}\left[i d_{k}\right]$.
(A), (B), and M4 imply that just after $p_{i}{ }^{\prime}$ 's neighbors have processed $p_{i}$ 's message, the lemma holds. As already seen in the proof of other lemmas, color_map ${ }_{j}\left[i d_{j}\right]$ may subsequently decrease, but never increases: colors can be suppressed from color_map $\left[i d_{j}\right]$ (line 30 ) but never added to it. And the same is true at $p_{i}$ for its set of colors color_map ${ }_{i}\left[i d_{i}\right]$, and at its parent $p_{k}$ for color_map ${ }_{k}\left[i d_{k}\right]$. It then follows that $\mid\left\{j: j \in\right.$ neighbors ${ }_{i} \wedge c \in$ colors $\left._{j}\right\} \mid \leq \gamma$ throughout the execution of the algorithm, which concludes the proof of the lemma.
$\square_{\text {Lemma } 6}$
Lemma 7. Algorithm 2 is $\gamma$-collision-free.
Proof We have to show that no process can have more than $\gamma$ of its neighbors broadcasting during the same round. Initially, all processes are in state 0 . Let us consider a process $p_{i}$ and assume that one of its neighbors $p_{j}$ is broadcasting a message. Let us further assume that this message is of type COLOR().

- If $p_{j}$ is $p_{i}{ }^{\prime}$ s parent, $p_{j}$ 's $\operatorname{COLOR}()$ message is the first message received by $p_{i}$, and both $p_{i}$ and its children ( $p_{i}$ 's remaining neighbors) are in state 0 , and hence silent. There is no collision at $p_{i}$.
- If $p_{j}$ is one of $p_{i}$ 's children, the value $\operatorname{slot}_{-} \operatorname{span}_{j}$ used by $p_{j}$ at line 31 is equal to max_cl contained in the mes- $^{\text {cos }}$ sage COLOR $\left(-,-, m a x_{-} c l\right)$ first received by $p_{j}$ from $p_{i}$. Because of Lemma 3, this message is well formed, and consequently satisfies property M6. Any other child $p_{\ell}$ of $p_{i}$ broadcasting during this round will have received the same first message, and will therefore be using the same slot_span ${ }_{\ell}=$ max_cl value. It follows from $^{\text {s }}$ Property M6, the assignment of line 11 executed by any child $p_{\ell}$ (of $p_{i}$ ) that received the message, and
the fact that its set colors $\ell$ can only decrease after being first assigned, that colors $_{\ell} \subseteq\left[0, \ldots\right.$, slot_span $_{\ell}-$ 1] for any child $p_{\ell}$ of $p_{i}(\mathrm{C})$.
Lemma 6, Property (C), and the $C L O C K$-based predicate defining the rounds at which a process is allowed to broadcast (line 31), imply that at most $\gamma$ children of $p_{i}$ can broadcast during the same round. If $p_{i}$ has a parent $p_{k}$ (i.e. $p_{i}$ is not the root), both $p_{i}$ and $p_{k}$ are in state 2 , and hence $p_{k}$ is silent, proving the lemma. If $p_{i}$ is the root, all its neighbors are its children, and the lemma also holds.
The same reasoning applies to the messages TERM() broadcast by the children of $p_{i}$ and its parent.
$\square_{\text {Lemma } 7}$
Lemma 8. Each process computes a set of colors, and the root process knows when coloring is terminated.

Proof Let us first observe that, due to Lemmas 2 and 3, no process $p_{i} \neq p_{r}$ can loop forever inside the while loop (lines 15-24), when it receives its first message $\operatorname{COLOR}()$. The same was proved for the root $p_{r}$ at the end of the proof of Lemma 4. Moreover, a process cannot block at line 30 when it receives other messages $\operatorname{COLOR}()$ (one from each of its children). Hence, no reception of a message $\operatorname{COLOR}()$ can prevent processes from terminating the processing of the message. The same is trivially true for the processing of a message TERM().

Let us first show that each process obtains a non-empty set of colors. To this end, we show that each non-leaf process broadcasts a message COLOR().

- When the root process $p_{r}$ receives the external message $\operatorname{START}()$, it "simulates the sending to itself" of the message COLOR $\left(i d_{r}\right.$, color_map $\left._{r}, \sigma_{r}\right)$, where the dictionary data structure color_map $p_{r}$ has a single element, namely, color_map $\left[i d_{r}\right]=\{1\}$ (line 11). The root $p_{r}$ executes consequently the lines $7-29$, during which it obtains a color, and computes a set of proposed colors color_map ${ }_{r}\left[i d_{j}\right]$ for each of its children $p_{j}$ (lines $25-$ 27). It then progresses to the local non-waiting state 1 (line 28). Hence, during the first round, it broadcasts to its neighbors the message $\operatorname{COLOR}\left(i d_{r}\right.$, color_map $\left._{r}, \sigma_{r}\right)$. Because the algorithm is conflict- and collision-free (Lemmas 1 and 5), this message is received by all the root's neighbors.
- Let us now consider a process $p_{i}$ that receives a message COLOR(sender, color_map, max_cl) for the first time. It follows from Lemma 4 that $p_{i}$ starts computing a non-empty set colors $_{i}$ and enters the waiting state 1 (line 28). Finally, as colors ${ }_{i} \subseteq[0, \ldots$, slot_span -1$]$, and $C L O C K$ never stops increasing, the predicate of line 31 is eventually satisfied. It follows that $p_{i}$ broadcasts the messageCOLOR $\left(i d_{i}\right.$, color_map $\left._{i}, \max _{-} c l_{i}\right)$. As above all of $p_{i}$ 's neighbors will receive this message.
It follows that $\operatorname{COLOR}()$ messages flood the tree from the root to the leaves.
Moreover, when a process $p_{i}$ has received a message COLOR() from each of its neighbors (children and parent), it has obtained the final value of its color set color_map ${ }_{i}\left[i d_{i}\right]=$ colors $_{i}$. Due to lemma 4, this set is not empty, which concludes the first part of the proof.

Let us now show that the root detects coloring termination. This relies on the messages TERM (). As previously, due to Lemma 1 and Lemma 7, these messages entail neither message conflicts nor message collisions.

Let us observe that each leaf process eventually enters the non-waiting state 3 . When the predicate of line 31 is satisfied at a leaf $p_{\ell}$ (this inevitably occurs), this process broadcasts the message TERM () to its parent $p_{i}$. Then, when $p_{i}$ has received a message $\operatorname{TERM}()$ from each of its children, it broadcasts TERM() to its own parent. This sequence repeats itself on each path from a leaf to the root. When the root has received a message $\operatorname{TERM}()$ from each of its children, it learns termination (line 40), which concludes the proof of the lemma.
$\square_{\text {Lemma } 8}$
Lemma 9. $\mid \bigcup_{1 \leq i \leq n}$ colors $_{i} \left\lvert\,=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1\right.$.
Proof Let $p_{r}, p_{a}, \cdots, p_{\ell}$ be a path in the tree starting at the root $p_{r}$ and ending at a leaf $p_{\ell}$. It follows from

- the content of the parameter max_cl of the messages COLOR(sender, cl_map, max_cl) that are broadcast along this path of the tree (broadcast at line 33 and received at line 5), and
- the assignment of $\max \left(\max _{-} c l, \sigma_{i}\right)$ to $\max _{-} c l_{i}$ at line 12 ,
that $m a x_{c} c l_{\ell}=\max \left(\sigma_{r}, \sigma_{a}, \cdots, \sigma_{\ell}\right)$. Let $p_{\ell 1}, \ldots, p_{\ell x}$ be the set of leaves of the tree. It follows that $\max \left(\max _{-} c l_{\ell 1}, \cdots, \max _{\_} c l_{\ell x}\right)=\max \left(\sigma_{1}, \cdots, \sigma_{n}\right)$, i.e., the value max_cl carried by any message is $\leq\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$.

The fact that a process $p_{i}$ uses only colors in $\left[0, \ldots,\left(\right.\right.$ max_ $\left.\left._{-} l_{i}-1\right)\right]$, combined with Theorem 1 implies the lemma. The algorithm is consequently optimal with respect to the number of colors.
$\square_{\text {Lemma }} 9$
Theorem 4. Let $K=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$. Algorithm 2 is a $\mathrm{C} 2 \gamma$-free algorithm, which solves $\mathrm{FBC}(n, \gamma, K, \geq 1)$ in tree networks. Moreover, it is optimal with respect to the value of $K$.

Proof The proof that Algorithm 2 terminates follows from Lemma 6. The proof that it is $\mathrm{C} 2 \gamma$-free follows from Lemma 1 and Lemma 7. The proof that it satisfies the Conflict-freedom, Collision-freedom, and Efficiency properties defining the $\operatorname{F3C}(n, \gamma, K, \geq 1)$ problem follows from Lemmas 2-6, and Lemma 9. The proof of its optimality with respect to $K$ follows also from Lemma $9 . \quad \square_{\text {Theorem } 4}$

## 8 EXPERIMENTAL EVALUATION

In this section, we evaluate experimentally our protocol using the OMNeT++ network simulator (version 5.3) [27], and compare its performance against that of the DRAND protocol [25], a reference distributed TDMA slot allocation algorithm. We have made the code we have used for our experiments publicly available on-line ${ }^{7}$.

### 8.1 The DRAND algorithm

DRAND uses a greedy color allocation strategy implemented with a fully decentralized control. It assumes a

[^3]

Figure 2. Execution time (measured in rounds) Figure 3. Number of broadcasts performed by Figure 4. Quality of the resulting TDMA schedof our F3C-algorithm and DRAND. On average, our solution is more than twice faster $(\times 2.11)$. our F3C-algorithm and DRAND. On average, ule. On average, our algorithm yields latency our algorithm uses 10 times fewer broadcasts. values that are $40 \%$ lower.

MAC (Medium Access Control) protocol to detect and avoid conflicts, and includes adaptive re-transmission mechanisms to tolerate collisions.

While in its initial state ('IDLE'), a DRAND node $p$ tosses an even coin. If $p$ gets head, it runs a lottery with a $\frac{1}{k}$ chance of success, where $k$ is the number of uncolored nodes in $p$ 's 2-hop neighborhood. If $p$ wins the lottery, it initiates a 2-phase commit negotiation with its neighbors in order to select an available time slot. This negotiation might fail if some neighbors are already involved in another 2-phase commit negotiation, in which case $p$ (the requesting node) returns to its IDLE state.

Because of its stochastic activation mechanism, and because the 2-phase commit phase may fail, DRAND is probabilistic by construction. It also does not avoid collisions while executing. For a conservative comparison, we have ignored collisions when simulating DRAND (we have let colliding broadcasts reach their destination), and have assumed that the underlying MAC protocol was perfect (thus avoiding conflicts).

### 8.2 Target network trees

We exercise both algorithms on randomly generated trees that exhibit a predetermined $\Delta$ (the maximum node degree), depth $d$, and size $n$. In the rest of the evaluation $\Delta$ is fixed at 7 , and depth at 6 . The trees are constructed recursively from the root node, choosing neighborhood sizes uniformly between 1 and $\Delta$ until a size of $n$ nodes is reached. We then prune trees whose maximum degree does not reach $\Delta$. Because DRAND is not designed to handle multiple channels, we assume $\gamma=1$ (only one channel is available) for a fair comparison.

### 8.3 Metrics

We evaluate our protocol and DRAND in terms of the following metrics:

- Execution time is the time each algorithm needs to allocate colors to all nodes in the network, measured in rounds.
- Broadcast complexity is the total number of broadcast operations performed by each algorithm.
- TDMA latency assesses the quality of the resulting coloring when interpreted as a TDMA schedule. TDMA
latency measures the average number of TDMA slots a node must wait before it is allowed to broadcast again.

### 8.4 Results

Figures 2 (Execution time), 3 (Broadcast complexity), and 4 (TDMA latency) show the results we obtain for network sizes varying from 50 to 500 nodes. In Figures 2 and 3 each point is averaged over 10 experiments, in Figure 4 over 20 experiments. Error bars show $95 \%$-level confidence intervals computed using Student's test statistics.

On all metrics, our F3C-algorithm clearly outperforms DRAND. DRAND is particularly hampered by its probabilistic nature, which slows it down (Figure 2), and causes it to use about ten times more messages than we do (Figure 3). In terms of schedule quality, both algorithms use the optimal number of colors/slots, $K=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1=\frac{7}{1}+1=8$. However, because our F3C-algorithm is able to assign (when possible) several colors/slots to individual nodes, F3C-nodes do not necessarily need to wait the repetition of the TDMA schedule to communicate again, yielding a decrease in latency of about $40 \%$ on average across all network sizes.

## 9 Conclusion

In this paper we investigated the problem of constructing a $\gamma$-frugal vertex coloring using a distributed algorithm experiencing conflicts and collisions. This problem arises in particular when assigning rounds (slots) to processes (nodes) in broadcast/receive TDMA wireless multi-channel networks in which each node only has access to one transceiver.

We presented a deterministic, distributed, parallel, coloroptimal, collision- and conflict-free algorithm which solves this distributed vertex-coloring problem for tree networks. This algorithm only uses $K=\left\lceil\frac{\Delta}{\gamma}\right\rceil+1$ colors (where $\Delta$ is the maximal degree of the graph), and is optimal with respect to the total number of colors that can be used. We have further evaluated the performance of this algorithm using simulations. The obtained experimental results show our solution clearly outperforms a reference protocol for distributed TDMA slot-allocation.

Moreover, from an algorithmic point of view, the proposed algorithm is versatile, making it an attractive starting point to address other related problems. For instance, in a heterogeneous network, lines $25-27$ could be modified to
take into account additional constraints arising from the capacities of individual nodes, such as their ability to use only certain frequencies.

Last but not least, a major challenge for future work consists in solving the F3C problem in general graphs using a parallel rather than sequential deterministic algorithm. The new difficulty is then to take into account cycles in a distributed setting in which the global graph topology is not known beforehand, but must be discovered on the fly while avoiding conflicts and collisions.

## AcKNOWLEDGMENTS

This work has been partially supported by the French ANR project DESCARTES (devoted to abstraction layers in distributed computing), and the Franco-Hong Kong ANR-RGC Joint Research Programme 12-IS02-004-02 CO2Dim.

Hicham Lakhlef has been an Associate Professor (Maître de Conférence) at the University of Technology of Compiegne (UMR CNRS 6174) in France since 2016. Prior to this, he was a postdoctoral researcher at the Université of Rennes 1 - IRISA (UMR CNRS 6074). He obtained his Ph.D. degree from the University of FrancheComté in 2014 in France. He obtained his Master's degree from the University of Picardie Jules Verne in 2011 in France. He served as a PC member for several conferences as IEEE EUROCON 2015, IEEE UIC 2016 and ICCS 2018.

Michel Raynal has been a professor of Informatics since 1981 (Sup Telecom Brest 1981-83, and then University of Rennes 1). Since 2013 he is also Chair Professor at the Polytechnic University of Hong Kong. His main interest lies in the fundamental principles that underlie the design and the construction of distributed computing. Professor Michel Raynal has published more than 150 papers in international journals (from JACM to IEEE Computer), and more than 300 papers in conferences. He has also written twelve books devoted to parallelism, distributed algorithms and systems (published by MIT Press, Wiley, Morgan \& Claypool and Springer).

François Taïani has been a Professor in Distributed Computer Systems at the University of Rennes 1 and IRISA/Inria in Brittany, France since 2012. Prior to that, he was with Lancaster University (UK) from 2005 to 2012. François holds a PhD from Université Toulouse III (2004), a Diplom der Informatik from Universität Stuttgart (1998), and a Diplôme d'Ingénieur from Ecole Centrale Paris (France). His main interest lies in the scalability and programmability of complex distributed systems (e.g. overlays, on-line social networks, data centers), with a focus on resilience, concurrency, and self-organization.
