ABSTRACT

Autonomy and the ability to maintain social activities can be challenging for people with disabilities experiencing reduced mobility. In the case of disabilities that impact mobility, power wheelchairs can help such people retain or regain autonomy. Nonetheless, driving a power wheelchair is a complex task that requires a combination of cognitive, visual and visuo-spatial abilities. In practice, people need to pass prior ability tests and driving training before being prescribed a power wheelchair by their therapist. Still, conventional training in occupational therapy can be insufficient for some people with severe cognitive and/or visuo-spatial functions. As such, these people are often prevented from obtaining a power wheelchair prescription from their therapist due to safety concerns. In this context, driving simulators might be efficient and promising tools to provide alternative, adaptive, flexible, and safe training. In previous work, we proposed a Virtual Reality (VR) driving simulator integrating vestibular feedback to simulate wheelchair motion sensations. The performance and acceptability of a VR simulator rely on satisfying user Quality of Experience (QoE). Therefore, our simulator is designed to give the user a high Sense of Presence (SoP) and low Cybersickness. This paper presents a pilot study assessing the impact of the vestibular feedback provided on user QoE. Participants were asked to perform a driving task whilst in the simulator under two conditions: with and without vestibular feedback. User QoE is assessed through subjective questionnaires measuring user SoP and cybersickness. The results show that vestibular feedback activation increases SoP and decreases cybersickness. This study constitutes a mandatory step before clinical trials and, as such, only enrolled people without disabilities.

Figure 1: Our power wheelchair driving simulator, composed of an HMD for visual immersion, a joystick to control the virtual power wheelchair, and a vestibular feedback platform.

1 INTRODUCTION

People with disabilities may experience mobility loss that can sometimes limit their ability to move around independently and retain access to social activities. Such limitations can be compensated by mobility aids such as power wheelchairs [10]. However, driving a power wheelchair is a challenging task that relies on good cognitive and visuo-spatial abilities especially when dealing with multiple dynamic obstacles outdoors or with door passing or narrow spaces indoors [22]. Thus, navigating safely requires a significant level of
expertise that can be achieved through efficient training, especially for people who have cognitive and visuo-spatial disabilities that prevent them from fully managing complex driving situations. Indeed, prescribers need to ensure that the powered mobility aid that they are to prescribe to the user will be operated safely in daily-life. If assessment and/or training is unsuccessful, therapists can decide to prevent wheelchair prescription to a patient for safety reasons.

To address this mobility issue for people who cannot operate a wheelchair safely, there are a plethora of works on driving assistance by means of autonomous solutions such as self-driving power wheelchairs [20]. However, such solutions are generally not adapted to therapists and end-users expectations and needs. Indeed, such autonomous solutions do not leave a sufficient amount of control to the user, which is however necessary to keep soliciting remaining functions and thus prevent loss of function. In addition, doing a task by oneself instead of having it done by a robot it has been shown empowering [15]. There also exist semi-autonomous solutions such as shared control or guidance systems [6, 9] that are more suited to user needs as they give a sufficient amount of control to the user. Indeed, with such systems, the user has full wheelchair control most of the time, and trajectory correction is applied only when there is a danger of collision. However, there are still no such solutions available on the market as they are still at the research stage. Moreover semi-autonomous systems that have currently been developed within research laboratories do not manage all types of complex situations. Indeed, current solutions mainly focus on avoiding obstacles within indoor environments [6, 42] and do not yet show sufficiently good performances in more complex situations such as navigation within complex urban environments [34], social interactions with pedestrians [11, 18], and negotiation of ramps or curbs [8]. Furthermore, these systems still require good driving skills by the user [20] and thus require training before they can be used in daily life.

Therefore, an alternative solution to navigation assistance systems is to acquire more driving skills by practising in training sessions, in particular in occupational therapy sessions where the user drives in ecological situations (daily-life situations). Nonetheless, these conventional training methods consisting in using a real wheelchair directly may not be adapted for people with severe visual and/or cognitive impairments [1]. Additionally, personalized training methods based on particular scenarios (e.g. at home, in hazardous situations, in crowded places) are too complex and costly to perform. In addition, some people with attention disorders may have great difficulty driving a wheelchair in ecological situations as they often have many distractions, multiple people moving around, and so on.

In this context, driving simulators are emerging to overcome these limitations and widen access to power wheelchair training. Indeed, simulation make it possible to perform various scenarios and assessment conditions within a safe, controllable and reproducible environment.

Virtual Reality (VR) makes it possible to build safe simulations and daily-life based scenarios [4]. Furthermore, VR has been shown to be efficient within a clinical context [5, 14]. Compared to other simulation tools, VR allows user immersion inside the Virtual Environment (VE), providing more Sense of Presence (SoP). SoP is the subjective phenomenon describing the user’s sense of “being there” in the VE [35]. In the case of wheelchair driving training, a high SoP will increase user ability to intuitively transpose safe driving skills acquired through virtual scenarios to real life situations [37].

However, completing a navigation task while immersed in a VE induces discomforts [19] often characterized as Cybersickness whose symptoms are similar to motion sickness (e.g. nausea, headaches, dizziness) [29]. Cybersickness is a major limitation on VR expansion since it significantly alters simulation comfort and user experience.

In previous work, we presented an innovative power wheelchair driving simulator for wheelchair training in VR [43]. Previous, present and future works dealing with driving simulators are conducted in close collaboration with a rehabilitation centre to better match the needs of wheelchair users with therapists, making our simulator relevant for actual end-users such as for the purpose of wheelchair training and assessment of driving abilities. Our simulator includes a mechanical platform that provides vestibular feedback and haptic feedback. The platform is able to simulate accelerations using the “tilt coordination” method [3] resulting from user command (vestibular feedback) or from physical response from the VE such as collisions (haptic feedback).

The objective of this paper is to investigate the contribution of vestibular feedback to SoP and Cybersickness in a multisensory driving experience. Indeed, we believe that reproducing real power wheelchair accelerations and centrifugal effects will enhance SoP while reducing perception discordance and Cybersickness. This study focuses on the impact of vestibular feedback for able-bodied people. It constitutes a first pilot study that enriches our expectations for future works, a basis for other studies on SoP with vestibular feedback and a necessary step before assessing the same assumptions for people with disabilities. This paper first introduces related work on VR and vestibular feedback. Second, it introduces our experimental study using a VR headset and our vestibular feedback platform. Third, we discuss our results and their validity. Finally, we present the conclusions of our work and future work directions.

2 RELATED WORK
This section presents the previous work concerning VR simulators. It then introduces two concepts related to VR experience: SoP and Cybersickness, and finally evaluate these concepts through experimental study.

2.1 VR Simulators
The field of VR regroups all computer-based techniques with the aim of simulating a 3D VE. Thus, such an environment is controllable, reproducible and safe. VR has major assets for building efficient tools known as simulators, largely used in training [16] and rehabilitation [14] programmes. Indeed, VR based simulators make it possible to build user-centered, ecological and specific situations. Therefore, the application of VR to power wheelchair simulation appears to be an excellent way to provide training with customized scenarios [2].
2.2 Sense of Presence

The efficiency of VR based simulation training strongly depends on SoP. SoP refers to the user’s sense of “being there” in the VE [35] and depends on various factors such as spatial presence, involvement and experienced realism [33]. The greater the SoP, the more the user will be involved and will learn from his or her virtual experience [37].

Several research projects have investigated ways to increase SoP. The driving simulator NADS Minisim [41] increases the user awareness component of SoP by providing additional haptic feedback information with the aim of enhancing user understanding of the surrounding environment while driving. Even in the entertainment field, a study of increased presence in cinema with additional feedback reveals positive results on user SoP [27].

Regarding wheelchair simulation, the single screen simulator ViEW [24] addresses SoP with user embodiment methods by representing the user’s hand in the VE. The miWe simulator also represents the user’s hand and investigates the impact of the use of a new wheelchair controller on SoP [38]. Finally, the addition of a feedback platform in the Virtual Fauteuil simulator [28] seems to contribute to a better immersion, and therefore to a better SoP.

2.3 Cybersickness

Even though VR is a great tool, early studies revealed that it suffers from Cybersickness, a major disadvantage [19]. Indeed, during a VR simulation, the user may experience Cybersickness, that is, discomforts similar to motion sickness symptoms (e.g., headaches, dizziness or nausea) [29]. Those discomforts arise from perception conflicts between what the user sees and feels, leading to cognitive mismatches. The greater mismatch between feedback in simulation and what is perceived in real experience, the more severe the Cybersickness.

In the context of a driving simulator, Cybersickness is more likely to arise as the user sees himself or herself moving, while not perceiving any physical motion. Niniss and Inoue [26] discuss this phenomenon, but never confirm any theory about the causes. Mahajan et al. [21] also observed Cybersickness effects when performing a study involving their wheelchair simulator. However, they did not assess the impact of their simulator platform on participant discomfort.

2.4 Assessing VR experience

SoP assessment is generally assessed through subjective questionnaires in the literature [25]. Participants answers to such questionnaires are commonly processed using the Wilcoxon signed rank non-parametric test [44]. Questionnaires such as NASA-TLX and IPQ, which aim to evaluate respectively cognitive load during a task and SoP, have been already used by VR and clinical specialists [12]. For instance, the IPQ was administered after users with disabilities used the miWe simulator to measure presence in the VE [38]. They used the IPQ to evaluate presence, spatial presence, involvement and realism separately. The IVEQ questionnaire [39] which tackles VR experience assessment is more recent, but can be used as it has already been validated. This questionnaire covers numerous aspects involved in user experience in VR such as immersion and experience consequences such as Cybersickness.

3 POWER WHEELCHAIR SIMULATOR

In previous work [43], we presented a VR-based power wheelchair simulator including an innovative motion feedback platform. This platform is a mechanical system with four degrees of freedom (DoF) (see Figure 2). The structure includes a parallel mechanism using 4 linear actuators (three DoF) and a turntable on the top (the fourth DoF). The platform size and weight are similar to power wheelchair standards. The platform aims to be compliant with standard wheelchair components such as the controller and seat. Indeed the mechanical platform is designed to accommodate standard wheelchair seating and control. Moreover, as people sometimes need an adapted controller to be able to drive the wheelchair, any type of controller can be plugged into the platform (e.g. joystick, head array, sip-and-puff, chin controls). For this experiment, the platform was equipped with an off-the-shelf wheelchair seat and a simple joystick controller coming from a Salsa M2 wheelchair. The four DoF of the platform make it possible to provide vestibular feedback by simulating wheelchair accelerations using the “tilt coordination” principle. This technique consists in using the gravitational force to trick the user vestibular system and simulating linear acceleration forces and centrifugal effects. For example, when the user accelerates in the forward direction, the platform will rotate around the pitch axis (illustrated in Figure 2) to mimic a backward force commonly experienced while accelerating in the forward direction with a real power wheelchair. The vestibular feedback includes acceleration effects simulated with the pitch axis and centrifugal effects simulated with the roll axis. The kinematic parameters that the platform can simulate have been experimentally obtained through a set of driving scenarios representing classical indoor and outdoor use cases.

While several simulators rely only on visual feedback [2], our platform allows the user to benefit from more modalities during the virtual experience. In order to increase SoP, the simulator platform is combined with a realistic VE and an immersive visual display technology (such as a Head Mounted Display, HMD). Moreover, the
addition of different feedback modalities should reduce mismatching of cognitive information and therefore Cybersickness.

Note that the “tilt coordination” principle also allows the platform to provide haptic feedback (forces induced by the VE such as a rough ground and virtual wheelchair interaction). This paper only focuses on the vestibular feedback impact on user experience during a wheelchair driving task in VR.

4 USER STUDY

4.1 Objective and Hypotheses

The objective of this paper is to assess the impact of the vestibular feedback provided by our simulator platform on SoP and Cybersickness during a wheelchair driving experience in VR. Positive results of this pilot study would advocate for the relevance of the proposed vestibular feedback modality for increasing user Quality of Experience (QoE). We enrolled only able-bodied participants in this experiment, even though our system is designed for people with disabilities. It is indeed necessary for our Research Ethics Committee that we validate system effectiveness and viability with able-bodied participants through a preliminary study before enrolling people with disabilities and end-users to assess the relevancy of such a simulator in training applications and improving wheelchair driving skills. Indeed, we need to prove and ensure user safety while using the simulator to obtain the Committee’s approval and run an experiment with people with disabilities. Moreover, testing a hypothesis in a pilot study with able-bodied people before using clinical patients as subjects is a commonly applied procedure [17, 30].

Based on previous works and our own VR experience, we define our hypotheses as follows:

**H1** The addition of vestibular feedback to visual feedback increases SoP for users. In particular, according to the Igroup project consortium (http://www.igroup.org/pq/ipq/index.php):

- **H1-Spa** This feedback increases spatial presence for users.
- **H1-Inv** This feedback increases user involvement.
- **H1-Rea** This feedback increases experienced realism for users.

**H2** The addition of vestibular feedback to the visual feedback decreases sensory conflicts and thus Cybersickness.

4.2 Apparatus

Our apparatus for this study corresponds to our multisensory power wheelchair driving simulator (see Figure 1). This simulator uses a Standard R-Net joystick for user input. We chose this device as it is a joystick commonly used to control standard power wheelchairs.

Concerning feedback, two devices are used to provide vestibular and visual feedback, respectively. The first device is the vestibular feedback platform, on top of which we set a standard wheelchair seat coming from a standard Salsa M power wheelchair. We provide a vestibular feedback using “tilt coordination”. In particular, we render linear accelerations using pitch, and centrifugal effects using roll, depending on both linear and angular speeds.

The second device is an HTC Vive HMD. HMD devices make it possible to immerse users in a VE, occulting the real world around them. As it covers all the user vision angles, it also enables users to look backward, which is important for reverse driving. In our case, this would also prevent participants from seeing the vestibular feedback platform movements. Besides, HMDs are largely used in the VR field and provide good head tracking as well as a suitable graphic rendering quality for an immersive experience.

Concerning the 3D environment, we used a 3D model of a flat square located in a French city. This square was mainly unfamiliar to participants as our experiment took place in another city. We added assets to this 3D VE to mark out a path that users had to follow in the experiment (see Figure 3). As users might not be familiar with power wheelchair driving, the speed limit of the virtual wheelchair was set to 0.86 m.s

4.3 Method

4.3.1 Participants. A total of 29, unpaid and able-bodied French-speaking participants were enrolled in this experiment. They were all naive to the purpose of the experiment. All of them signed a consent form explaining the running of the experiment to them. It was also explained to them that they could ask to stop the experiment whenever they wanted. In order for our experiment to be reliable, we applied a strict validation policy. This policy will be explained in details in Section 5. In total, we removed 13 participants. Then, 16 people (average age of 28.6, SD = 12.33, min = 19, max = 60) were kept in the analysis. 13 of them were males, and 3 were females. 14 were right-handed.

On average, the participants had little experience with virtual reality and dynamic seats. Most of them had an intermediate to high level of experience with video games. Only one participant had an intermediate level of experience with power wheelchair driving. We conducted this experiment with participants from a different city from the one reproduced in our VE. This was intended to prevent participants from noticing differences between the scene and the real place (i.e. the real place was often crowded while no pedestrians were present in the virtual scene). Only one participant knew the real version of the VE in which participants were asked to perform the driving task.
4.3.2 Experimental conditions. We aimed to determine the impact of our platform’s vestibular feedback on SoP and Cybersickness during a wheelchair driving task in VR. For this experiment, we identified two experimental conditions:

- **C_V**: No vestibular feedback. Participants were only provided with visual feedback through the HMD.
- **C_M**: With vestibular feedback. Participants were provided with visual and vestibular multisensory feedback.

Each participant completed two trials during this experiment, one for each of the two experimental conditions. The order of presentation was counterbalanced across participants (Eight participants were presented with C_V first, and eight with C_M first).

4.3.3 Measures. In order to assess our hypotheses and the impact of our platform vestibular feedback on user QoE, we collected subjective evaluations from participants using three subjective questionnaires, all previously validated in French:

- The NASA Task Load Index (NASA-TLX) [13]. This questionnaire was used to determine whether the presence of the vestibular feedback would alter the cognitive load of the user.
- The Igroup Presence Questionnaire (IPQ) [32]. This questionnaire allows spatial presence, involvement, and experienced realism to be assessed.
- The Immersive Virtual Environments Questionnaire (IVEQ) [39, 40]. We used all measures concerning immersion, presence, engagement, and experience effects.

The participants completed each of the three questionnaires after each experimental condition.

4.3.4 Experimental Procedure. Participants were asked to sit on the wheelchair seat attached to the vestibular feedback platform. They were given time to familiarize themselves with the VE before starting the driving task. They were invited to start the driving task whenever they were ready to. The trial automatically stopped once they reached the end of the path. They were then taken to another room to fill out the questionnaires assessing user experience in this first trial. This prevented them from seeing the vestibular feedback platform moving when changing the experimental condition. Once they had completed the questionnaires, they performed the second trial. At the end of the second trial, they filled in the same questionnaires again to evaluate their QoE in the second trial.

4.3.5 Virtual Driving Task. As shown in Figure 4, the virtual driving task consists of a sequenced path to be completed inside the virtual scene representing a city square. The path starts at point A and ends at point B, moving over symbols. Each symbol represents a specific instruction as presented in Table 1. Note that every symbol should be rolled over. The constructed path includes a lot of action in order to increase acceleration variation to ensure user involvement during the driving task, but also to ensure that users perceive the vestibular feedback while following the path.

5 RESULTS AND ANALYSIS

This section presents our validation policy to ensure that our results were unbiased for the analysis. Then, we will present the results obtained through the three questionnaires for the analysis of SoP and Cybersickness, according to the two investigated experimental conditions.

5.1 Validation policy

Analysing subjective user perceptions such as the SoP required the experiment to be unbiased regarding (1) knowledge related to the vestibular feedback provided and (2) perceptive biases that could have occurred during the experiment. We removed two participants from the experiment after they reported having previously observed the vestibular feedback platform while operating during demonstrations. We then removed additional participants according to three identified perceptive biases they experienced during trials. Firstly, three participants experienced visual discomforts (such as lags or bad quality settings). This might have decreased the immersion. Secondly, six participants might have heard surrounding noises (such as human voices coming from people not involved in the study) despite the earmuff. This might have influenced their SoP along with their focus on the virtual driving task. Finally, two participants decided on their own to park by moving forward against instructions. As such, they did not experience all expected feedback and their data were discarded from analysis.

After selecting the participants for the analysis, we ensured that the duration of trials completed by the participants was sufficient...

for them to potentially experience SoP and Cybersickness. Participants completed each trial in 119 s on average (SD=28 s). No significant difference was found between the first and second trials. The duration of trials was sufficient for participants to potentially experience both SoP and Cybersickness as the exposure time does not affect these two components of VR experience [23].

For each item of the three questionnaires, we compared the intra-subject answers depending on the type of feedback. This section presents only the significant results obtained using a Wilcoxon signed-rank test, related to our hypotheses (see Table 2 and Figure 5). The questionnaire items were presented in their French-validated versions to our participants, but for readability purposes we provide their English-validated equivalent here.

5.2 Sense of Presence

5.2.1 Spatial presence. Concerning the IVEQ, for item 1(fr)/2(en) “My interactions with the virtual environment seemed natural.”, participants reported significantly higher ratings for the C\textsubscript{M} condition. These results support H1-Spa.

5.2.2 Involvement. Concerning the IPQ, for item INV3 (“I still paid attention to the real environment.”), participants reported significantly lower ratings in the C\textsubscript{M} condition. For item INV4 (“I was completely captivated by the virtual world.”), participants reported higher ratings in the C\textsubscript{M} condition. Concerning the IVEQ, for item 5(fr)/6(en) (“The sense of moving around inside the virtual environment was compelling”), participants reported higher ratings in the C\textsubscript{M} condition. For item 15(fr)/19(en) (“I became so involved in the virtual environment that it was as if I was inside the game rather than manipulating a gamepad and watching a screen.”), participants reported higher ratings in the C\textsubscript{M} condition. These results support H1-Inv.

5.2.3 Experienced realism. Concerning the IPQ, for item REAL2 (“How much did your experience in the virtual environment seem consistent with your real world experience?”), participants reported higher ratings in the C\textsubscript{M} condition. This results support H1-Rea.

All components of SoP (Spatial presence, Involvement and Experienced realism) presented a significant enhancement through the addition of our vestibular feedback. Thus, these results support our global hypothesis H1 concerning SoP.

5.3 Cybersickness

Concerning the IVEQ, for item 61(fr)/70(en) (“I suffered from vertigo during my interaction with the virtual environment.”), participants reported lower ratings in the C\textsubscript{M} condition. Besides, one of our participants reported in open feedback that “the simulation without movements was not pleasant and disrupted the brain”. These results support H2 concerning Cybersickness.

Concerning the TLX, for item (“How insecure, discouraged, irritated, stressed and annoyed were you?”), participants reported lower ratings in the C\textsubscript{M} condition. Besides, multiple participants reported in open feedback having preferred the trial with the vestibular feedback. This suggests that our vestibular feedback globally enhanced quality of the VR experience for our participants.
6 DISCUSSION
This section discusses three aspects of our research: the user study, the simulator and observations on SoP and Cybersickness. Future works will also be revealed.

6.1 User study
After applying a strict validation policy and despite the number of participants retained for results analysis, we collected and analysed enough data to obtain significant results. Indeed, the Wilcoxon signed-rank test is a non-parametric test, which implies that no difference between groups could have been established without a consequent effect size. However, a larger set of participants would allow us to investigate the influence of user characteristics (e.g. age, gender, habits, experience) on driving behaviour. Furthermore, this pilot study only involved able-bodied participants, who are not the target population for a wheelchair driving simulator. However, such a study with able-bodied participants constitutes the very first step before assessing our hypotheses with people with disabilities. On the one hand, this is because we have to validate the relevancy of the simulator modalities provided (here, the vestibular feedback). On the other hand, it is mandatory to perform such a preliminary study with able-bodied participants in order to obtain authorizations from the Research Ethics Committee to initiate clinical investigations with people with disabilities. Although the study was not performed with the targeted population, the results remain valid and usable in other projects.

Despite the fact that participants were not acquainted with the city from which the virtual scene had been modelled, the fact that it represents a real world city square contributes to the realism of the environment. Elements used to mark the path for users to follow were inspired by real world objects (barriers and cones), and the arrows were designed to look like tags on the ground. This ensured that the whole environment was as realistic as possible to enhance user SoP. As the path and environment were the same in both conditions, significant differences found for SoP and Cybersickness cannot be explained by their variations. The path was also complex enough to ensure the diversity of vestibular feedback presented to users (e.g. accelerations, brakes, slight and sharp turns, reverse driving). Furthermore, we chose to limit the experiment driving speed (0.86 m.s$^{-1}$) to half the average speed of a real power wheelchair. Indeed, a higher speed induces higher accelerations and thus provides an easier way to stimulate the vestibular system and to reduce Cybersickness. Thus, we believe that if vestibular stimulation works at low speed, it will work even better at high speed. Plus, our simulator’s target audience is mainly first-time power wheelchair users, who are more likely to drive slower than experienced users. Finally, this scene suffers from a major drawback: the lack of dynamic elements and features. The participants were alone in the scene, while the existing place is usually crowded. The reproduced scene was therefore not entirely ecological. This shows that we ensured that participants had little chance of already

![Figure 5: Reported ratings showing significant differences between CV and CM. Scales are displayed in vertical axis.](image-url)
knowing the place. It would be interesting to conduct an experiment with pedestrians and cars to better immerse participants in the VE.

6.2 Simulator and vestibular feedback

Our simulator benefited from the dual contribution of computer and mechanical scientists to design and build the vestibular feedback platform. We aim to increase our simulator performances over time, in terms of BOTH feedback and physical behaviour. It is important to note that we only added vestibular feedback for this study while our feedback platform is also able to simulate haptic and auditory feedback. Indeed, in order to avoid bias and ensure that only the impact of vestibular feedback was evaluated, we turned the haptic feedback off as it is not being evaluated yet. However, once the user is driving at maximum speed, the power wheelchair is no longer subject to accelerations. Thus, the user does not feel any vestibular feedback. This is why we maximized the number of actions that induced acceleration variations during virtual task.

Compared to other types of existing feedback modalities, the main objective of our vestibular feedback is not to give additional information to the user or to help in the navigation [7]. The proposed feedback only provides a consistent and realistic wheelchair behavior in order to decrease Cybersickness, increase SoP and thus enhance the VR experience. However, future works on haptic feedback will provide additional relevant information regarding both the navigation and QoE improvements as haptic feedback concerns reactions to the VE.

6.3 SoP and Cybersickness

Most of the other simulators aim to analyse the issues related to the use of a wheelchair in an urban environment, or to assess training possibilities [24, 28]. To the best of our knowledge, there is no other study investigating the impact of vestibular feedback on SoP and Cybersickness in VR.

However, we believe that SoP and Cybersickness are key elements in simulator based training. On the one hand, SoP is linked to spatial presence and experienced realism, but also user involvement and motivation, which is known to be an important factor for training [36]. On the other hand, reducing Cybersickness is critical to increase user QoE since most users would not be able to use VR for training purposes due to Cybersickness symptoms. Thus, SoP and Cybersickness are key elements to be addressed for a high quality of virtual experience [39].

It is also interesting to point out that while our study concerned a power wheelchair driving task, the presented results remain valid and usable in other projects. In particular, every VR based simulator could benefit from the addition of vestibular feedback. Also, further investigation of vestibular feedback as additional information should be interesting in domains like robot teleoperation and tele-presence such as in [31]. It could enhance the quality and precision of manoeuvres for real robot experienced operators as they will retrieve realistic sensations.

7 CONCLUSION AND FUTURE WORKS

In this paper, we used our power wheelchair driving simulator to conduct a pilot study assessing the impact of the vestibular feedback provided on user SoP and Cybersickness during a driving task in VR. Participants were asked to drive the virtual power wheelchair along a path in a VE reproducing a real city square. Every participant completed the path twice in a counterbalanced order: one with visual feedback only, and one with visual and vestibular feedback. We used subjective questionnaires (NASA-TLX, IPQ and IVEQ) to assess the quality of the VR experience after completion of each task.

The results validate our stated hypotheses: the addition of the vestibular feedback to the visual feedback provided by the visual display interface rendering the VE increases SoP and decreases Cybersickness for users. Therefore, the vestibular feedback contributes to better user QoE while using the simulator to drive a wheelchair in a VE. Those positive results imply that the simulator is more likely to be accepted and used by the targeted population (therapists and end-users). Indeed, the positive impact of the proposed vestibular feedback on increased SoP (by 2.44/10) and reduced Cybersickness provides solutions to deal with issues such as user lack of involvement and Cybersickness effects that represent important barriers to the use of VR technology by this target population. In a nutshell, our results highlight the importance of providing vestibular feedback in increasing the quality of VR experience and therefore the benefit of our simulator for training and rehabilitation programmes.

This first pilot study paves the way towards numerous studies and research. In future works, the impact many parameters such as average speed, virtual environment or participant history should be investigated. In particular, it would be interesting to collect and analyse objective measures (e.g. gaze direction, electrodermal activity) to objectively quantify the impact of the vestibular feedback on SoP and Cybersickness and to complete the subjective assessment that we presented in this paper. Concerning participant history and susceptibility to cybersickness we plan to use Motion Sickness Susceptibility Questionnaire (MSSQ) with a reduced number of questions by using more precise scales such as Simulator Sickness Questionnaire (SSQ) instead of IVEQ. Also, some guidelines for future works can be drawn from non significant results with low p-value like the IVEQ-13 item “the simulation without movements was not pleasant and disrupted the brain” which draws our attention to the possible importance of the ecological aspect of the virtual environment.

We also plan to validate our hypotheses for the haptic feedback component of the vestibular feedback platform, corresponding to the vibrations caused by the road on the wheels while driving, among others. Finally, we plan to enroll participants with disabilities to confirm the presented result for target population and make comparisons between their driving behavior and performances with our simulator and a real power wheelchair. This would pave the way for the use of our simulator for training and rehabilitation applications.
