Ankle, hip and stepping strategies for humanoid balance recovery with a single Model Predictive Control scheme

Zohaib Aftab, Thomas Robert and Pierre-Brice Wieber

Abstract—While humans are highly efficient in dealing with balance perturbations, current biped humanoid robots are far from showing similar skills. This is mainly due to the limited capacity of current robot controllers to deal with the inherently complex dynamics of biped robots. Though Model Predictive Control schemes have shown improved robustness to perturbations, they still suffer from a few shortcomings such as not considering the upper body inertial effects or non-optimal step durations. We propose here a Model Predictive Control scheme that specifically addresses these shortcomings and generates human-like responses to perturbations, involving appropriate combinations of ankle, hip and stepping strategies, with automatically adjusted step durations. The emphasis of this paper is on modeling and analyzing the effects of different cost functions and coefficients on the behavior of the controller while leaving real-time implementations and experiments for later work.

I. Introduction

Recovering balance after a perturbation occurs can be a complex process involving different strategies depending on the situation. Experimental study of this process in humans has led to identify three basic strategies, the ankle, hip and stepping strategies [1], [2]. It has been observed that the ankle and hip strategies work in parallel to recover balance, the amplitude of the hip strategy being positively scaled with the amplitude of the perturbation [3], [4]. The stepping strategy is only triggered in case of stronger perturbations, but below the theoretical stability limit of the previous strategies, so that appropriate combinations of the three strategies are generated in order to recover effectively with suitable step length and duration.

Current biped robots are still far from showing similar versatile and efficient responses to perturbations. Although the hip strategy has been demonstrated to considerably enhance the stability of biped systems through the use of the upper-body inertia [5], [6] most biped control schemes only implement the ankle strategy, only regulating the Center of Pressure (CoP) with feet positions fixed in advance [7], [8], [9]. Stepping strategies have already been addressed with the Capture Point and similar concepts [10], [11], [12], [13], [14] or with a Linear Model Predictive Control (LMPC) scheme including future steps as potential control variables [15].

But all of these schemes suffer from the same common limitations:

Z. Aftab and T. Robert are with the IFSTTAR - Université Lyon 1, LBMC UMR_T9406, France. P.-B. Wieber is with the Bipop team at INRIA Rhône-Alpes, France. zohaib.aftab@ifsttar.fr, thomas.robert@ifsttar.fr, pierre-brice.wieber@inria.fr

– when the hip strategy is considered, a sequential transition from ankle to hip strategy is usually implied by saturation or arbitrary thresholding [16], [17], [18],
– the step duration, which has a strong impact on the efficiency of the balance recovery, is always estimated or fixed in advance, which can be seriously limiting,
– except for [10] and the LMPC scheme [15], all the stepping strategies mentioned earlier require that the biped system stops in exactly one step, what is neither always feasible nor desirable.

Our goal here is to propose an efficient balance recovery scheme implementing an appropriate combination of ankle, hip and stepping strategies. Such a combination has already been obtained in simulation in [19] and the results were impressive, but with a heuristic approach lacking both the provable stability and the optimality that we are looking for with our LMPC scheme. A similar combination has also been discussed in [20], but without much details ("distribute the high frequency components to the flywheel and the low frequency components to the inverted pendulum") and therefore without much analysis.

Of all the balance controllers discussed above, the LMPC scheme proposed in [15] is the most promising technique in our view since it deals naturally with multiple step strategies thanks to the calculations over a future horizon of time. We will use it therefore as our main building block, and amend it to offset its different shortcomings exposed above, namely:

– we will integrate upper body inertial effects in order to generate appropriate combinations of hip strategies with the ankle and stepping strategies already appearing in [15],
– we will integrate a proper optimization of the step duration for improved efficiency of the balance recovery behavior.

We are going to present this amended MPC scheme in the next Section, analyze the optimization of the step duration in Section III and demonstrate in Section IV how the ankle, hip and stepping strategies are eventually combined to generate efficient balance recovery behaviors.

II. An MPC scheme for balance recovery

A. Dynamic model and prediction horizon

A well regarded simple model of human and humanoid balance is the Linear Inverted Pendulum (LIP) where the whole mass m of the system is considered concentrated at the Center of Mass (CoM), moving at a constant height h above the ground [21]. Since we're also interested here in

the effect of trunk rotations on balance, we supplement this LIP model with a simple flywheel model as in [5] and [22], leading to the simple linear dynamics

$$mh\ddot{c} + j\ddot{\theta} = mg(c - z) \qquad (1)$$

where c and z are the horizontal coordinates of the CoM and CoP, θ is the orientation of the trunk, j the inertia of the trunk and g the norm of the gravity force.

The controller design initially proposed in [23] and further refined in [15] and [24] is based on anticipating future motions on a prediction horizon composed of N time intervals of equal length T. The motion on this future horizon is considered having a piecewise constant third derivative $\dddot{c}$ and $\dddot{\theta}$ over each time interval. Considering the state

$$\hat{c}_k = \begin{bmatrix} c_k \\ \dot{c}_k \\ \ddot{c}_k \end{bmatrix}, \hat{\theta}_k = \begin{bmatrix} \theta_k \\ \dot{\theta}_k \\ \ddot{\theta}_k \end{bmatrix} \qquad (2)$$

of the system at a time t_k, all it takes is a straightforward time integration to relate the position, speed and acceleration of the CoM over the whole prediction horizon

$$C_{k+1} = \begin{bmatrix} c_{k+1} \\ \vdots \\ c_{k+N} \end{bmatrix}, \dot{C}_{k+1} = \begin{bmatrix} \dot{c}_{k+1} \\ \vdots \\ \dot{c}_{k+N} \end{bmatrix}, \ddot{C}_{k+1} = \begin{bmatrix} \ddot{c}_{k+1} \\ \vdots \\ \ddot{c}_{k+N} \end{bmatrix} \qquad (3)$$

to the piecewise constant third derivative

$$\dddot{C}_{k+1} = \begin{bmatrix} \dddot{c}_{k+1} \\ \vdots \\ \dddot{c}_{k+N} \end{bmatrix} \qquad (4)$$

through simple matrices:

$$C_{k+1} = S_p \hat{c}_k + U_p \dddot{C}_k, \qquad (5)$$
$$\dot{C}_{k+1} = S_v \hat{c}_k + U_v \dddot{C}_k, \qquad (6)$$
$$\ddot{C}_{k+1} = S_a \hat{c}_k + U_a \dddot{C}_k. \qquad (7)$$

Detailed formulas for these matrices can be found in [15]. Identical relationships obviously hold for the trunk rotation θ.

The linear dynamics (1) can be reversed to compute the position of the CoP from the motion of the human or humanoid system:

$$z = c - \frac{h}{g}\ddot{c} - \frac{j}{mg}\ddot{\theta}. \qquad (8)$$

As before, we can easily relate the position of the CoP over the whole prediction horizon

$$Z_{k+1} = \begin{bmatrix} z_{k+1} \\ \vdots \\ z_{k+N} \end{bmatrix} \qquad (9)$$

to the piecewise constant third derivatives $\dddot{C}_k$ and $\dddot{\Theta}_k$ through simple matrices:

$$Z_{k+1} = S_z \begin{bmatrix} \hat{c}_k \\ \hat{\theta}_k \end{bmatrix} + U_z \begin{bmatrix} \dddot{C}_k \\ \dddot{\Theta}_k \end{bmatrix}, \qquad (10)$$

TABLE I: Anthropomorphic proportions used in the simulation

Variable	Symbol	Value	Ref.
Body height	H	1.76 m	
Body mass	m	76 kg	
CoM height	$h = 0.575 \times H$	1.012 m	[25]
Foot length	$0.152 \times H$	0.268 m	[25]
Max trunk rotation	θ_{max} (forward)	$\pi/2$ rad	
Min trunk rotation	θ_{min} (backward)	$-\pi/3$ rad	
Trunk inertia	j	8 kg.m^2	[25]
Max hip torque	τ_{max}	190 N.m	[26]
Control weight	α_1	1 m.s^{-1}	
Control weight	α_2	10 rad.s^{-1}	
Control weight	α_3	200 m.s^{-2}	
Control weight	α_4	100 m.s^{-3}	
Control weight	α_5	300 rad.s^{-3}	
Control weight	α_6	100 m	

with

$$S_z = \begin{bmatrix} S_p - \frac{h}{g}S_a & -\frac{j}{mg}S_a \end{bmatrix}, \qquad (11)$$

$$U_z = \begin{bmatrix} U_p - \frac{h}{g}U_a & -\frac{j}{mg}U_a \end{bmatrix}. \qquad (12)$$

B. Kinematic and dynamic constraints

The dynamics (1) of human and humanoid balance is subject to a series of kinematic and dynamic constraints that have to be satisfied over the whole prediction horizon, for all $i \in [k+1, \dots k+N]$. For example, trunk rotation is limited by articulation constraints. With such a simple model, it will be constrained by direct bounds

$$\theta_{min} \leq \theta_i \leq \theta_{max}. \qquad (13)$$

The same concerning hip torques:

$$j|\ddot{\theta}_i| \leq \tau_{max} \qquad (14)$$

(values for all the geometric and dynamic parameters of the model are gathered in Table I).

If f_i represents the horizontal position of the support foot on the ground at time t_i, the maximum extension of the support leg can be simply enforced with the horizontal position of the CoM:

$$\|c_i - f_i\| \leq l_{max}. \qquad (15)$$

If f'_i represents the horizontal position of the swing foot above the ground, its acceleration will also be bounded:

$$\|\ddot{f}'_i\| \leq \ddot{f}'_{max}. \qquad (16)$$

Finally, the CoP z is also constrained to stay within the boundaries of the support polygon, what can be expressed in the following way:

$$D(z_i - f_i) \leq b, \qquad (17)$$

where D and b are a matrix and a vector encoding the shape of the foot with respect to the position f_i of the support foot on the ground (more details can be found in [24]).

In order to express these constraints over the whole prediction horizon, we have to relate the position of the support foot over the whole prediction horizon

$$F_{k+1} = \begin{bmatrix} f_{k+1} \\ \vdots \\ f_{k+N} \end{bmatrix} \quad (18)$$

with the current support foot position f_k which is fixed on the ground and the positions $\bar{F}_{k+1}$ of the future steps which will have to be decided by the balance controller. This can be done easily with matrices V_{k+1} and $\bar{V}_{k+1}$ filled with 0s and 1s simply indicating which sampling times t_i fall within which steps (more details can be found in [24]):

$$F_{k+1} = V_{k+1}f_k + \bar{V}_{k+1}\bar{F}_{k+1}. \quad (19)$$

C. Controller design

Following the controller design proposed in [15] and [24], we consider an MPC scheme that anticipates future motions over a prediction horizon. We are interested in regulating the balance of a humanoid system standing still and experiencing perturbations of various amplitude. The basic objective is therefore to minimize the speed $\dot{C}_{k+1}$ of the CoM and the rotation speed $\dot{\Theta}_{k+1}$ of the trunk over the prediction horizon while taking care of all the constraints listed earlier. Minimizing the acceleration $\ddot{F}'_{k+1}$ of the swing foot will appear to be valuable as well in the next Section, leading to a multi-objective controller minimizing a weighted sum

$$\min \ \frac{1}{\alpha_1^2}\|\dot{C}_{k+1}\|^2 + \frac{1}{\alpha_2^2}\|\dot{\Theta}_{k+1}\|^2 + \frac{1}{\alpha_3^2}\|\ddot{F}'_{k+1}\|^2. \quad (20)$$

But following the analysis developed in [15], the resulting motions appear to be significantly improved when minimizing also the third derivatives $\dddot{C}_k$ and $\dddot{\Theta}_k$ of the motion and the distance between the position Z_{k+1} of the CoP and the center F_{k+1} of the support foot. The final multi-objective controller looks therefore to minimize

$$\min \ \frac{1}{\alpha_1^2}\|\dot{C}_{k+1}\|^2 + \frac{1}{\alpha_2^2}\|\dot{\Theta}_{k+1}\|^2 + \frac{1}{\alpha_3^2}\|\ddot{F}'_{k+1}\|^2$$
$$+ \frac{1}{\alpha_4^2}\|\dddot{C}_k\|^2 + \frac{1}{\alpha_5^2}\|\dddot{\Theta}_k\|^2 + \frac{1}{\alpha_6^2}\|Z_{k+1} - F_{k+1}\|^2, \quad (21)$$

with weights α_1 to α_6 chosen with respect to the magnitude of the associated terms and their importance in the balance recovery process. Typical values are given in Table I.

As noted in [15], the third derivatives are weakly penalized (relatively high weights α_4 and α_5) only to smooth the resulting motion, with relatively low impact on the final behavior of the robot. Same thing with the final term and weight α_6 which loosely centers the CoP in the support polygon. More important is the penalization of the trunk rotation speed with respect to the CoM speed, which affects how much trunk rotation is used. For a reference weight α_1 of 1 m.s^{-1}, reasonable values for α_2 are around 3 to 30 rad.s^{-1}. Most important in this paper is the weight α_3, the effect of which will be analyzed in more depths in the following Sections.

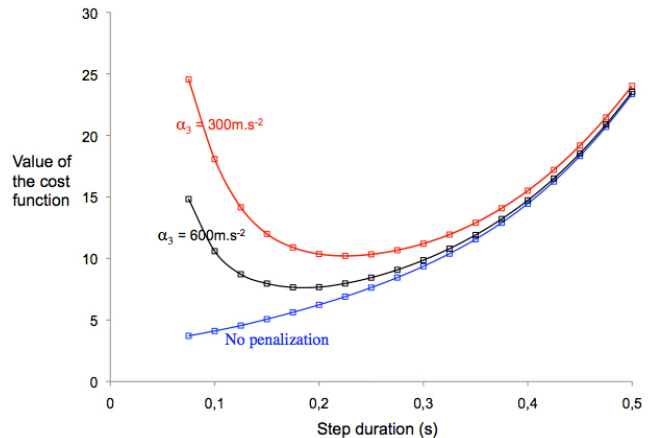

Fig. 1: Minimal value of the objective function for different penalization coefficients α_3, or for no penalization at all of the swing foot acceleration $\ddot{F}'_{k+1}$, for a given perturbation and different fixed step durations.

Since this controller only deals with the cartesian positions of the CoM and feet and orientation of the trunk, mapping these variables with the whole body motion of the articulated robot is done with classical Forward and Inverse Kinematics methods. The motion of the feet is interpolated with 5th degree polynomials between their current position, velocity and acceleration and their desired position on the ground with zero velocity and acceleration (no impact).

In the following Sections, this multi-objective controller will be considered only in the sagittal plane, with a prediction horizon of length 1 s (N = 20, T = 0.05 s). The situation will be that of a human sized model standing still with both legs aligned in the sagittal plane, experiencing impact disturbances of varying amplitude.

III. REGULATING THE STEP DURATION

Recovering from perturbations with automatic step placement has already been realized successfully in [27], [15] and [24] with MPC schemes similar to the one presented here, but always with a fixed step duration. Yet, the adaptation of the step duration is at least as important as the adaptation of the step placement when having to recover from perturbations. Allowing the duration of the steps to vary has been tried in [28], but the steps ended up being always chosen the quickest possible: if no explicit lower limit was set on their duration, they were chosen to be infinitely quick!

The reason for this ill behavior lies in the objective function which was the same as the one proposed here in (21), but without penalizing the acceleration $\ddot{F}'_{k+1}$ of the swing foot. Let's have a look at the value of this objective function as a function of step duration in Fig. 1 for a post-impact CoM velocity of 1 m.s^{-1}. We can observe that when the acceleration of the swing foot is not penalized, this objective function decreases continuously with shorter step durations: quicker steps always allow minimizing CoM and trunk rotation speeds more and more efficiently. But quicker
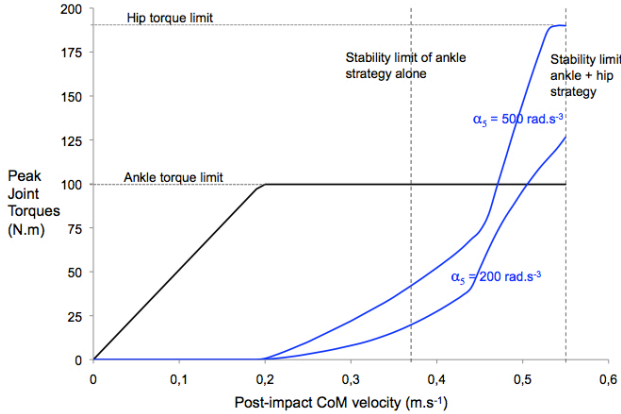

Fig. 2: Combination of ankle and hip strategies when feet are kept on the ground (no stepping). The disturbance is characterized by the post-impact CoM velocity. Resulting recovery response is plotted in terms of peak ankle and hip torques.

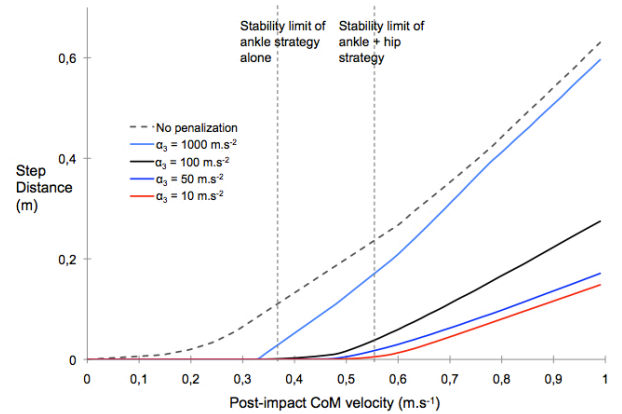

Fig. 3: Step length when reacting to varying post-impact CoM velocities for different penalization coefficients α_3, or for no penalization at all of the swing foot acceleration $\ddot{F}'_{k+1}$. The step duration is fixed to 0.3 s.

steps incur a mechanical and energetic cost [29], [30] which should be put in balance with the balance recovery objective.

We propose here to introduce a simple model of this mechanical cost in the objective function (21) by penalizing the acceleration $\ddot{F}'_{k+1}$ of the swing foot. We consider moreover in (16) that this acceleration can't anyway exceed a given maximum value. We can see in Fig. 1 that this combined objective function rises steeply for very quick steps: its minimum is now reached for intermediate step durations, which will depend on the coefficient α_3. For the example depicted in Fig. 1, minimizing the combined objective function (21) with a coefficient α_3 equal to 300 m.s^{-2} selects a step duration of 0.23 s.

Note that allowing the duration of the steps to vary makes the optimization problem (21) become nonlinear, requiring more complex numerical solvers. In the case of an MPC scheme like here, this nonlinear optimization problem needs to be solved at high frequency for proper feedback efficiency since it is evolving with time as the current state of the system is evolving. Hopefully, parametric Sequential Quadratic Programming (SQP) algorithms allow to solve such evolving nonlinear problems at a relatively low computational cost [31]. Initial numerical experiments showed that we could solve the nonlinear MPC scheme presented here in less than 10 ms, with room for improvement, so real-time implementations are largely within reach [28]. But we propose to focus here on the modeling issue, analyzing the effects of different cost functions and coefficients on the behavior of the controller, leaving real-time implementations and experiments for later work.

IV. MULTIPLE BALANCE RECOVERY STRATEGIES

Let's analyze first how the ankle and hip strategies combine in our controller when the feet are kept on the ground (no stepping) and the system is exposed to impacts of various magnitudes. We can see in Figure 2 that for small perturbations, the ankle strategy is used increasingly until

it reaches its limit torque. If this ankle strategy is used alone, a stability limit is reached for a post-impact CoM velocity of approximately 0.37 m.s^{-1}. When the hip strategy is combined with the ankle strategy, they work in parallel to recover balance even if the stability limit of the ankle strategy alone hasn't been reached yet, and the amplitude of the hip strategy is positively scaled with the amplitude of the perturbation, similarly to what has been observed in humans [3], [4]. Together, these two strategies allow recovering from much stronger perturbations, with post-impact CoM velocities up to 0.55 m.s^{-1}.

Let's complete now the balance recovery behavior with the stepping strategy. In order to analyze how the three strategies combine, let's consider first a situation where the step duration is fixed to 0.3 s. We can see in Figure 3 that if the acceleration $\ddot{F}''_{k+1}$ of the swing foot is not penalized, the stepping strategy is initiated even for the smallest perturbations, what isn't a reasonable behavior. This parallels the discussion we already had in Section III: if the stepping strategy incurs no cost, then there's no reason not to put it at work, even when it's absolutely not necessary nor even particularly helpful.

Depending on how much this acceleration is penalized, the stepping strategy will be activated at different levels of perturbations, as we can see once again in Figure 3. For a small penalization ($\alpha_3 = 1000$ m.s^{-2}), the stepping strategy is initiated before even reaching the stability limit of the ankle strategy alone. For a strong penalization ($\alpha_3 = 10$ m.s^{-2}), it is initiated only when reaching the stability limit of the ankle and hip strategies working together. We can tune therefore very easily when the decision is taken to use the stepping strategy, and how much.

Let's combine now these three strategies with the regulation of the step durations and consider a situation where our model is standing still, upright while a force of 1.5 times its weight is applied horizontally forward during 0.05 s at the level of its CoM. All parameters are set according to
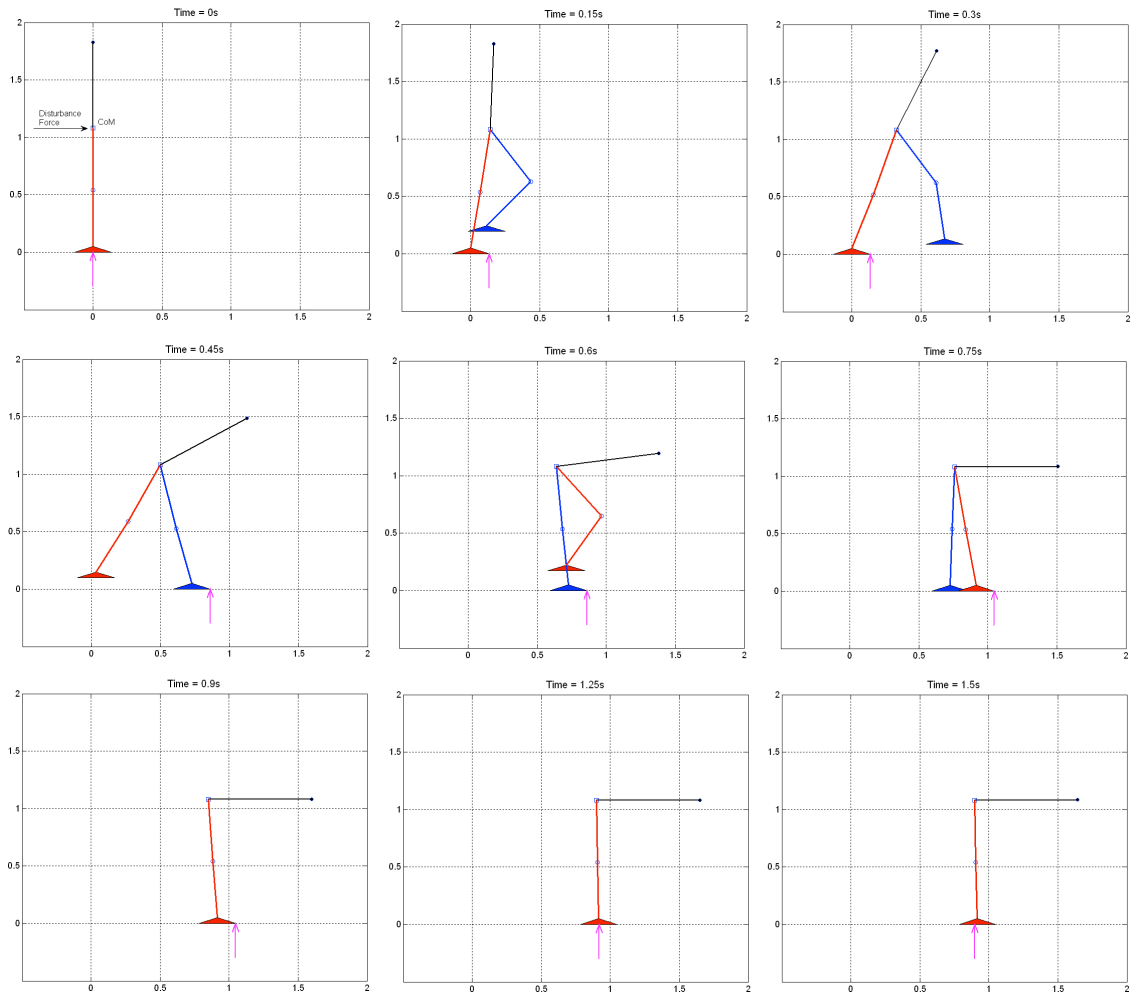

Fig. 4: Snapshots of a balance recovery motion combining ankle, hip and stepping strategies after a force of 1.5 times its weight applies horizontally forward during 0.05 s at the level of the CoM. Position of the CoP is indicated by an arrow below the feet.

Fig. 5: Evolution with time of the positions of the CoM in black and CoP in blue during a balance recovery simulation (top left). Red and blue vertical segments precise the rhythm and positions of the steps, the gray zone emphasizing the support polygon on the ground. Corresponding evolution of CoM velocity (bottom left), upper body rotational acceleration (top right) and position (bottom right).

Table I. The resulting balance recovery behavior can be seen in Figure 4, with corresponding plots displayed in Figure 5. The system recovers successfully and stops completely after 2 steps of durations 0.35 and 0.3 s, followed by a final grouping of the feet. The trunk accelerates forward during the first step to absorb the perturbation, then decelerates to avoid exceeding its maximum angle. The CoP remains most of the time at the toes during the recovery phase for maximal CoM deceleration, and goes back to the middle of the feet at the end of the motion. All in all, our scheme demonstrates a stable recovery behavior combining all 3 strategies naturally and efficiently.

Note that the final position is with a trunk bent forward close to its maximum angle ($\pi/2$) since the goal of the controller (21) is only to decelerate the CoM and trunk rotation, without specifying any desired final position and angle.

V. CONCLUSION

We presented in this article an MPC scheme that demonstrates biped balance recovery response to external perturbations by intelligently using the 3 basic strategies observed in humans. We showed how different strategies can be effectively regulated by adjusting relative weight coefficient values in the optimization criterion. In addition, the step durations were also optimized by simply penalizing the acceleration of the swing foot. Finally the simulation result demonstrated a stable recovery response to a large external disturbance to the standing posture. Future work is aimed at extending this scheme to tackle external perturbations during walking and the implementation of these ideas on a real robot.
