PROJECTIVE DYNAMICS, dry frictional contact scenarios, even at a modest number of iterations (20 iterations here). Compared to reference implicit contact solvers of the literature (here, ARGUS [Li et al. 2018] in inset, with fixed mesh resolution), it performs an order of magnitude faster while generating similar visual effects at the macroscopic scale.

In this paper we propose a simple yet effective method to integrate in a unified and semi-implicit way contact as well as dry frictional forces into the nested architecture of Projective dynamics. Assuming that contacts apply to nodes only, the key is to split the global matrix into a diagonal and a positive matrix, and use this splitting in the local step so as to make a good prediction of frictional contact forces at next iteration. Each frictional contact force is refined independently in the local step, while the original efficient structure of the global step is left unchanged. We apply our algorithm to cloth simulation and show that contact and dry friction can be captured at a reasonable precision within a few iterations only, hence one order of magnitude faster compared to global implicit contact solvers of the literature.

INTRODUCTION

Properly accounting for contact and friction is a major challenge when simulating dynamic solid objects, such as 3D soft bodies, cloth, or hair. During motion, objects should not interpenetrate, but still interact in a stable way. At contact, they should dissipate energy in a realistic manner, following the Coulomb law for dry friction, which captures the typical threshold effect between stick and slip. In the last decades, a number of implicit algorithms have been designed so as to satisfy these major requirements in a stable and robust way [Daviet et al. 2011; Li et al. 2018; Otaduy et al. 2009]. However, such solvers currently remain inaccessible to interactive scenarios. Instead, interactivity is often obtained at the price of a simplification and/or a decoupled treatment of the interaction framework considered adding a quadratic penalty energy to the global system, which however broke the simple – constant matrix – structure of the global linear equation, while failing to treat contact in an implicit manner.

Consistently degradable model. Simulating complex deformable objects in a both realistic and interactive fashion is more than ever a topical issue, as new applications like virtual try on or fast prototyping, requiring both faithfulness and speed, are being deployed [Barthé et al. 2016; Wang 2018]. In addition, possessing tools to design an animation sequence interactively before proceeding to (offline) high-accuracy simulation constitutes a longstanding issue in the field of feature film production [Barbić et al. 2012]. In all cases, having access to a consistently degradable model, that is, a discrete model which converges to the desired continuous model while generating satisfactory (in a sense to be defined) simulations at low cost, is truly beneficial. In our case, we will qualify a simulation of satisfactory
it yields visually convincing motions while being free of popping artifacts; and, in case of contact, if it strictly avoids penetration while qualitatively matching sticking and sliding behaviors compared to the high precision simulation.

**Projective dynamics framework.** In the case of nodal and contact-free systems, Projective dynamics [Bouaziz et al. 2014] appears as an interesting degradable model, able to yield an accurate solution to the dynamics if enough time budget is allocated, while computing an approximate yet stable solution in a very short amount of time – almost one order of magnitude faster compared to an incomplete Newton solve reaching the same precision. The key of the method is to approximate internal forces as linear terms of the positions, and to alternate iteratively between fast (linear) implicit global solves and local projection steps where forces are refined in parallel.

The common way to handle contact in that framework is to add a stiff elastic potential which penalizes interpenetrating vertices [Bouaziz et al. 2014]. However, the frequent activation/deactivation of contacts prevents from an efficient prefactoring of the global step, thus downgrading the overall performance of the base algorithm unless parallel GPU-based strategies are designed [Fratarcani et al. 2016; Komaritzan and Botsch 2019; Wang 2015]. Moreover, as contact is handled explicitly, weights associated to the contact forces must be chosen carefully to avoid penetration and popping artifacts. Finally, we are not aware of any algorithm incorporating dry friction in that framework. Recent attempts to include dry friction rely on the more general ADMM framework [Brown et al. 2018; Overby et al. 2017] and are not directly transferable to Projective dynamics. Besides, in these works, friction is decoupled from the normal force at each iteration, so that frictional contact is properly captured only when converging at a good precision. In contrast, in our approach we treat contact and friction simultaneously, while fully relying on the light and simple Projective dynamics framework.

**Contribution.** We propose a robust and efficient decoupled algorithm for incorporating frictional contact forces into Projective dynamics while keeping the global matrix constant. Assuming that contacts apply to nodes only, we rely on a simple splitting strategy in the local step so as to satisfy simultaneously non-penetration and Coulomb constraints, in a semi-implicit way (Section 3). Additionally, we extend our approach to self-contacts and carefully design a contact sorting scheme to handle multiple contact stacking in a stable way (Section 4). We obtain satisfactory simulations within 10 to 30 local/global iterations, even for complex scenarios involving multiple self-contact layers, and finally show that our method reaches a ×15 to ×36 speed gain compared to the reference code ARGUS [Li et al. 2018] used with fixed resolution (Section 5).

## 2 BACKGROUND

We consider a nodal system made of $m$ vertices whose positions $q(t)$ and velocities $v(t) = \frac{dq}{dt}$ are two functions from $\mathbb{R}^3$ to $\mathbb{R}^{3m}$. The system is subject to uniform external forces $f_{\text{ext}}(t)$, such as gravity, as well as to stiff internal forces $f_{\text{int}}(q(t))$, such as elastic forces, assumed to be position-dependent, as in [Bouaziz et al. 2014]. The system may also undergo unknown frictional contact forces so as to satisfy constraints for non-penetration and Coulomb friction.

### 2.1 Implicit integration without contact

The time evolution of the system is dictated by the Newton second law, which is discretized in time using the implicit Euler scheme,

$$\begin{align*}
q_{n+1} &= q_n + hv_{n+1} \\
v_{n+1} &= v_n + hM^{-1}(f_{\text{int}}(q_{n+1}) + f_{\text{ext}})
\end{align*}$$

where $h > 0$ is the integration timestep, $(q_n, v_n) \in \mathbb{R}^{3m} \times \mathbb{R}^{3m}$ the state of the system at discrete time $t_n$, and $M$ the (positive) diagonal mass matrix of the nodal system, of size $(3m, 3m)$.

**Optimization view.** We further assume, as in [Bouaziz et al. 2014], that internal forces derive from a potential energy, so that $f_{\text{int}}(q) = -\sum_i \nabla W_i(q)$. Equation (1) can then be interpreted as the necessary optimal conditions of the following optimization problem,

$$\min_{q_{n+1}} \frac{1}{2h^2} (q_{n+1} - s_n)^T M (q_{n+1} - s_n) + \sum_i W_i (q_{n+1})$$

where $s_n = q_n + hv_n + h^2M^{-1}f_{\text{ext}}$. Projective dynamics [Bouaziz et al. 2014] computes an approximate yet stable solution to this problem that is almost one order of magnitude faster compared to a Newton solve with similarly low precision (see Section 2.3).

### 2.2 Implicit integration with frictional contact

We now assume the system to be subject to $N_c$ dry frictional contacts $j = 1, \ldots, N_c$. Non-penetration constraints together with Coulomb friction conditions are compactly expressed by the so-called Signorini–Coulomb law. For each contact $j$, the Signorini–Coulomb law constrains each pair of relative velocity $u_j \in \mathbb{R}^3$ and local contact force $f_j \in \mathbb{R}^3$ at contact $j$ (i.e. the relative velocity and contact force expressed in the local contact basis $R_j$, see inset figure) to lie in a certain set $C_j$, such that $(f_j, u_j) \in C_j$ if and only if

take off $f_j = 0$ and $u_j \in N_j \geq 0$,

or (stick) $\|f_j\| \leq \mu_j |u_j| N_j$ and $u_j = 0$,

or (slip) $\|f_j\| \leq \mu_j |u_j| N_j$, $u_j \in N_j = 0$, and $\exists \sigma_j > 0$, $f_j = -\sigma_j u_j |T|$,

where the normal and tangential components of any local vector $y_j \in \mathbb{R}^3$ are denoted by $y_j |N = y_j R_j e_j \in \mathbb{R}$ and $y_j |T = y_j - y_j |N R_j e_j \in \mathbb{R}^3$, respectively, with $e_j$ the contact normal expressed in the world frame (hence $R_j e_j$ is the local contact normal).

The Signorini–Coulomb law captures three disjoint cases: taking-off, sticking, and slipping (see inset figure). We refer the reader to [Broglia 2016; Daviet et al. 2011] for more details and various equivalent formulations of this law.

**Implicit integration problem.** Following Moreau’s implicit time-stepping scheme [1988], the dynamic equations can be integrated over an arbitrary time step $h$ as

$$\begin{align*}
q_{n+1} &= q_n + hv_{n+1} \\
v_{n+1} &= v_n + hM^{-1}(f_{\text{int}}(q_{n+1}) + f_{\text{ext}} + \frac{f_j \xi(R_j)}{R_j}) \\
u_{n+1} &= Jv_{n+1} + u_f \\
V &= 1 : N_c : (f_{n+1} |_{R_j}, u_{n+1} |_{R_j}) \in C_j
\end{align*}$$

\[\xi = \begin{cases} 1 & \text{contact is active} \\ 0 & \text{contact is inactive} \end{cases}\]
where a global unknown force $\xi(r_{n+1})$, stemming from the Signorini-Coulomb constraint (3d), has been added to the linear momentum equation (3b). A linear kinematic law (3c) relates node velocities $v \in \mathbb{R}^{3n}$ to contact velocities $u \in \mathbb{R}^{3N_c}$ through the gradient matrix at contact $J = \frac{\partial f}{\partial u}$ of size $(3N_c, 3m)$. The constant term $u_f$ is the value of $u$ when $v = 0$, for example, in the presence of external moving obstacles. Compared to Equation (1), the set of unknowns has been augmented in Equation (3) since now, not only the $m$ node velocities $v$ have to be solved for, but also the $N_c$ local contact velocities and forces, $u \in \mathbb{R}^{3N_c}$ and $r \in \mathbb{R}^{3N_c}$.

A common way to solve the discrete frictional contact problem (3) robustly is first to linearize the internal force in (3b), then eliminate $v$ by introducing the so-called Delassus operator $D := JM^{-1}J^T$, and finally employ an implicit nonsmooth solver of the literature [Daviet et al. 2011; Jean 1999; Kaufman et al. 2008; Otaduy et al. 2009] to solve the problem in $(u, r)$. Of course this solving can be performed iteratively while linearizing the internal forces. Overall, such a method can be seen as an extension of the Newton method for a constrained system, hence it is not well-suited for fast simulation. In the following, we mention two interesting views of the problem which will help us design an accelerated algorithm for solving (3), in line with Projective dynamics.

Optimization view. Interestingly, Cadoux and colleagues [Acary et al. 2011; Cadoux 2009] have extended the common optimization interpretation of constraint-free implicit dynamics, recalled in Section 2.1, to the case of frictional contact. They have recast System (3) as a sequence of quadratic problems subject to conical constraints. Each iteration is much simpler to solve compared to the full problem, but it still remains costly compared to a linear solve. Inspired by this approach, and motivated by the gain of efficiency at low resolution, we have striven to design yet another iterative algorithm, leading this time to a linear global step.

Special case of a nodal system. It is noteworthy that in the case of a nodal system with contact occurring at nodes only, the gradient $J$ takes a simple form as each one of its $3N_c$ lines $j$ contains one non-zero $3 \times 3$ block at index $3i$ consisting of the transposed local basis $R_j$ of contact $j$ at node $i$, such that $u_j = (R_j)^T v_i + u_{n,j}$. Daviet et al. [2015] have exploited this property to build an accelerated solver dedicated to nodal systems, which was then improved and combined with adaptive simulation [Li et al. 2018]. In that framework however, self-contacts cannot be incorporated easily as they break the simple invertible structure of $J$. To keep the simple structure of $J$, the authors suggest duplicating nodes sharing several contacts, and linking them through artificial pin constraints. This new set of constraints however considerably increases the solving cost. In contrast, our local contact algorithm supports several contacts per node, and proves extremely stable even at low precision (see Section 4).

2.3 Projective dynamics method

Projective dynamics [Bouaziz et al. 2014] has striven to outperform the traditional Newton method for solving the contact-free dynamics (1), at least in the range of low precision. The general idea is to reformulate the optimization problem (2) as a sequence of constraint-free quadratic programs with constant symmetric positive-definite matrix $P$ - or equivalently, to reformulate the nonlinear equation (1) as a sequence of linear problems $P_{q_{n+1}} = b$. To achieve this goal, the key is to express potential energies $W_i$ as quadratic distance measures with respect to an (unknown) rest state $p_i \in E_i$,

$$W_i(q, p_i) = \frac{\omega_i}{2} \| A_i S_i q - B_i p_i \|^2 + \delta_{E_i}(p_i).$$

where $A_i$, $B_i$ and $S_i$ are constant matrices, $\omega_i$ is a nonnegative weight, and $\delta_{E_i}$ is the characteristic function of the set $E_i$ (in the sense of convex analysis), that is, $\delta_{E_i}(p_i) = 0$ if $p_i \in E_i$, and $\delta_{E_i}(p_i) = +\infty$ otherwise. This way, nonlinearity of the internal forces $f_{int}$ w.r.t. $q$ is transferred to the local search of a suitable rest state $p_i$, by solving, at fixed $q$, each local and independent subproblem

$$\min_{p_i} W_i(q, p_i) = \min_{p_i \in E_i} \frac{\omega_i}{2} \| A_i S_i q - B_i p_i \|^2. \quad (4)$$

Main algorithm. The Projective dynamics method then boils down to an iterative algorithm alternating between parallel local solves of optimization problems (4) and the global solve of the linear system

$$\begin{align*}
M + h^2 \sum_i \omega_i S_i^T A_i^T A_i S_i & q_{n+1} = M s_n + h^2 \sum_i \omega_i S_i^T A_i^T B_i p_i, \\
& p \leftarrow b_n^{-1}(p).
\end{align*} \quad (5)$$

As local solves can be done in parallel and the global solve can benefit from a single precomputation of the constant inverse $P^{-1}$, the method proves to be extremely fast in the absence of contact, even for a high number of degrees of freedom. The iterative Projective dynamics algorithm is outlined in Algorithm 1 (in black), with our modifications (in orange).

**Algorithm 1:** Algorithm of Projective Dynamics for computing positions and velocities at time $t_{n+1}$, augmented with our computation of frictional contact forces.

$q_{n+1}^0 \leftarrow q_n + h v_n + h^2 M^{-1} f_{ext};$

Detect the contacts;

Sort self-contacts (see section 4.2);

for $k$ from 0 to $\max_{iter} - 1$ do

| Project $q_{n+1}^k$ to obtain $q_{n+1}^{k+1}$ using (4);
| Compute and add the friction forces (see sections 3.3 and 4);
| Solve the linear system (5) with fixed $p_{n+1}^{k+1}$ to obtain $q_{n+1}^{k+1}$;

end

$q_{n+1} \leftarrow q_{n+1}^{\max_{iter}};

v_{n+1} \leftarrow \frac{1}{h} (q_{n+1} - q_n);$

Adding contacts. As mentioned earlier, in [Bouaziz et al. 2014] non-penetration is handled by adding a new elastic potential which pulls out the involved vertices. However, this scheme modifies the left-hand side of the global step, and thus removes the benefit of factorizing $P^{-1}$ once for all. Furthermore, as contact forces are computed as explicit penalties, they may require a careful and scenario-dependent tuning of their associated weight to prevent interpenetration effectively. Finally, dry friction cannot be enforced robustly with this scheme. We depart from this approach and in the same spirit as what was recently done in the context of ADMM [Brown et al. 2018; Overby et al. 2017], we compute the unknown frictional contact forces by refining them progressively in the local step. In
contrast to the latter works however, we fully couple the normal and tangential components of each force, and compute the resultant in a semi-implicit way. This allows us to fulfill the Signorini-Coulomb constraints satisfactorily even at a low number of iterations.

3 SIGNORINI-COULOMB IN PROJECTIVE DYNAMICS

3.1 Velocity-based Projective dynamics

As seen in Section 2.2, the Signorini-Coulomb constraints are preferably expressed in terms of velocities (not positions). To include these constraints to the Projective dynamics framework, we thus start by reformulating the Projective dynamics algorithm in terms of velocities. While the local solves (4) are left unchanged, the global linear system (5) becomes

$$ b_n(p) = \frac{1}{h} (b_n(p) - Pq_n). $$

We denote by $b_n(p)$ the new right-hand side term of the dynamics, given in Equation (6). Note that apart from this modification, the global solve is identical to the original system (5) expressed on positions. Finally, after having computed the new velocities $\nu_{n+1}$, positions $q_{n+1}$ are updated trivially as $q_{n+1} = q_n + h\nu_{n+1}$. In practice, we have not noted any difference in the results yielded by this velocity-based algorithm compared to the original one.

3.2 Local vs global constraints

As in Section 2.2, we now consider the nodal system to be subject to $N_c$ frictional contacts. For the moment we limit ourselves to the case where each contact $j$ occurs between a single node $i$ and a still obstacle (nodal contact, no self-contact and $u^k_i = 0$). We shall only consider nodal contact in this paper but will alleviate other assumptions in Section 4.

As we now focus on the iterations of Projective dynamics, at fixed time step $n+1$, we drop the $n+1$ index from our notation for the sake of clarity. Local/global iterations of the Projective dynamics algorithm will be denoted by the letter $k$.

The dynamic equations (3) include a new force $\xi$, the global contact force, which is related to the unknown local contact forces $r$ through the matrix $J$. If the node $i$ is involved in a contact $j$, then $\xi_j = R_j r_j$, where $R_j$ is the local contact basis of $j$. Otherwise, $\xi_j = 0$.

**First idea: global constraint.** A straightforward idea is to note that at iteration $k+1$, once the $p^k_i$ have been updated, the global solve takes the form of a linearized dynamic equation subject to the Signorini-Coulomb constraints,

$$ \begin{align*}
    \nu^{k+1} &= b(p) + \xi(r^{k+1}) \\
    u^{k+1} &= Jv^{k+1} + u^k \\
    \forall j = 1 \ldots N_c, (r_j^{k+1}, u_j^{k+1}) &\in C_{p^k_j},
\end{align*} $$

with the velocities $v^{k+1}$, $u^{k+1}$ and the contact impulses $r^{k+1}$ as unknowns. Hence, we could use an implicit frictional contact solver of the literature, for instance the nodal solver of [Daviet et al. 2015; Li et al. 2018] to solve the global step. Although such a method works well, we have unfortunately observed that the global step is slowed down by a factor 15, which makes it hardly compatible with interactive needs even for a low number of iterations.

Second idea: progressive refinement of the local contact forces. Observing Equation (7), we note that similarly to internal forces which depend on the local unknowns $p_j$, the global contact force depends on the local unknowns $r_j$. Our idea is thus to progressively refine the value of $\xi(r)$, by updating locally the values of the $r_j$, at each iteration of Projective dynamics. That is, starting from the local step at iteration $k$, we first compute the $p^{k+1}$ as in [Bouaziz et al. 2014], which are simply denoted by $p$ in the following. Then, we aim at computing the $r^{k+1}$ in parallel (in a manner that remains to be defined). If all these local solves can be done properly, the complex global solve (7) can be replaced with the following linear global solve, $\nu^{k+1} = b(p) + \xi(r)$, which has exactly the same cost as the original global solve of Projective dynamics without contact.

We now explain how the contact forces can indeed be updated locally to approach the Signorini-Coulomb constraints globally.

3.3 Local update of the frictional contact forces

Our goal is to update the frictional contact forces $r_j$ so that each pair $(u_j^{k+1}, r_j^{k+1})$ satisfies the Signorini-Coulomb law at iteration $k + 1$. Unlike the minimization of distance potentials, the Signorini-Coulomb law involves velocities $v$ of the body as we have $u_j = (R_j)^Tv$. To obtain stable results even at low precision, we propose to do this update semi-implicitly. To this aim, we seek to find an approximate equation relating $u_j$ to $r_j$ for each contact $j$, and then set the values of $r_j$ so as to satisfy the Signorini-Coulomb constraint at each contact.

**Splitting scheme.** Inspired by the popular Jacobi scheme for solving linear systems, our key idea is to approximate Equation (7a) through a splitting operation. More precisely, we search for a decomposition of $P$ as a sum of a positive diagonal matrix and a positive matrix. Such a decomposition is straightforward, as we readily have $P = M + C$ with $M$ the (diagonal positive) mass-matrix, and $C = h^2\sum_i\omega_i S_i^T A_i^T A_i S_i$ a positive matrix. At iteration $k + 1$ we thus obtain the splitting scheme

$$ M v^{k+1} = b(p) - C v^k + \xi(r^{k+1}), $$

yielding the nodal equation

$$ \forall 0 \leq i \leq m \quad M_i v_i^{k+1} = \begin{cases} f_i & \text{if } i \text{ not in contact} \\ f_i + R J f_i & \text{if } i \text{ in contact } j, \end{cases} $$

where $M_i > 0$ is the mass of the $i$th node.

For each contacting node $j$ (involved in the contact $j$), we use the nodal contact assumption $u_j = (R_j)^Tv_j$ and finally obtain an approximate local equation relating $u_j$ to $r_j$ at next iteration $k + 1$,

$$ \forall 0 \leq j \leq N_c \quad M_j u_j^{k+1} = R J f_j + r_j^{k+1}. $$

**Enforcing Signorini-Coulomb.** We can now enforce the Signorini-Coulomb law at iteration $k + 1$ by examining the normal and tangential components of the term $d_j$. Indeed,

- If $d_j/N \geq 0$ then the body should be taking off at next iteration, that is, we set $r_j^{k+1} = 0$ (and we indeed have $u_j^{k+1} \geq 0$);

ACM Trans. Graph., Vol. 39, No. 4, Article 57. Publication date: July 2020.

4.2 Dealing with multiple contacts per node
To overcome this issue, we sort the contact forces in several "layers" (batches) that are processed sequentially to avoid inconsistencies, while forces in the same layer can safely be processed in parallel. More precisely, we process the list of contacts and organize them as follows:

- Contacts between two nodes that are not involved in other contacts are safe and added to the first parallel batch (1);
- Contact between a node and an external obstacle are also added to the first layer (1). Indeed, the external object does not react to contact forces applied on it; the latter can thus serve as the “origin” for the next layers (inset figure, left);
- Then we process the remaining contacts by traversing our graph of contacts, and build the different contact “layers”;
- Finally, for layers of self-contacts that are not in contact with an external object, we start arbitrarily from one "side" and build the layers through to the other side (inset figure, right).

5 RESULTS AND COMPARISONS
We have implemented the Projective dynamics algorithm in C/C++ using OpenMP for parallelization. Collision detection is performed through simple proximity queries, using an acceleration structure. All the examples were run on a desktop computer featuring 4 dual-core Intel i7-5600U processors running at 2.60GHz.

Examples. Our results focus on cloth examples, which are particularly challenging in terms of frictional contact, but our technique is general and can be applied to any nodal system satisfying Projective dynamics energies. We have tested our method on five scenarios:

- **Ribbon**: a ribbon falling on an inclined plane, causing multiple layered self-contacts;
- **Square1**: a flat sheet falling on a rotating sphere, showcasing impacts and frictional contact with a moving obstacle;
- **Square3**: three stacked flat sheets falling on a rotating sphere, involving additional multi-layered contact compared to the previous example;
- **Arabesque**: the dress of a dancing character, freely available from [Li et al. 2018], combining impacts with a moving obstacle and stick-slip thresholding behavior;
- **Crinoline**: a highly-detailed gown with puff sleeves and complex folds, subject to walking and turning motions.

Table 1 gives the configuration for each one of these scenarios. For better realism in Arabesque and Crinoline, we added air damping forces modeled explicitly as \( \varepsilon \dot{v}_j = -\gamma v_j \) for each non-contacting node, with \( \gamma \) the damping coefficient.

Sample images of our examples are provided in Figures 3 and 4. Please also refer to the accompanying video for the full animations.

5.1 Qualitative evaluation

Influence of the number of iterations. Figure 2 shows the effect of varying the number of global/local iterations for Ribbon and Square1. For both examples, simulations degrade consistently down to 10 iterations, below which Square1 stops converging properly, while Ribbon continues to work consistently. In terms of accuracy, no significant difference is observed above 20 iterations. In the sequel, we thus chose 20 iterations for these two examples along with Square3. For Arabesque and Crinoline, which involve higher resolution meshes and stiffer materials, we used 30 iterations.

Varying the friction coefficient and comparison with Argus. As shown in Figure 3, we have run our four examples with both low and large values of the friction coefficient to demonstrate the macroscopic impact of sticking vs. sliding behaviors. We have reproduced these experiments using the accurate and freely available Argus simulator [Li et al. 2018], using the same timesteps and a fixed mesh resolution. Due to the specific form of energies required by Projective dynamics, we were not able to match exactly the same material parameters as those used for Argus, but we picked stretching and bending weights so as to obtain a reasonable match. Despite these differences in material, it is noteworthy that the response to frictional contact yielded by our method is similar to that generated by Argus, as shown in our accompanying video. Moreover, in case of multi-layered contacts, Argus in its fixed resolution version depicts some obvious artifacts (presumably due to an overly coarse mesh resolution in folding areas), whereas our method generates perfectly stable results.

Fig. 2. Simulating the Ribbon (left, \( \mu = 0.3 \)) and Square1 (right, \( \mu = 0.1 \)) examples using a various number of iterations. In green: 5 iterations, in light blue: 10 iterations, in dark blue: 20 iterations, in purple: 30 iterations.

Fig. 3. Varying the friction coefficient in our four examples Ribbon (\( \mu = 0.3 \) and \( \mu = 0.6 \)), Square1 and Square3 (\( \mu = 0.1 \) and \( \mu = 0.3 \)), and Arabesque (\( \mu = 0.0 \) and \( \mu = 0.3 \)), using 20 to 30 iterations per timestep. Results are visually close to those generated by the accurate Argus simulator [Li et al. 2018] (see accompanying video), while being computed 15 to 36 times faster.

5.2 Convergence

Analytical example. As in [Li et al. 2018], we have evaluated our method on the scenario of a falling sheet parallel to an inclined plane, illustrated in Figures 5a and 5b. In this setup, an analytical model for the dynamic of the nodes can be derived, and we show in Figures 5c and 5d that our numerical results match the analytical curves. Moreover, we have measured a global penetration and friction error using the so-called Alart-Curnier function [Alart and Curnier 1991; Bertails-Descoubes et al. 2011] and we have found out that, in this simple scenario, for each time-step the error vanishes after just one local/global iteration. Indeed, as all nodes have the same motion due to the initial configuration, no internal force is applied, i.e. the terms in C in both sides of the equation cancel each other, meaning that no error is introduced by the splitting scheme.

General case. In most of the cases where the terms in C are not negligible, our scheme still manages to decrease the Alart-Curnier error, yielding the visually good results described in Section 5.1.

In Figure 6, we show the evolution of the normal and tangential errors (i.e. the amount of deviation from the non-penetration and Coulomb friction constraints, respectively) w.r.t. the number of iterations for four different time steps selected from the Sphere1 example. We see that both errors quickly decrease in the first iterations, before reaching a plateau at moderate precision with a much lower slope. Also note that the tangential part responsively adjusts to the bound set by the normal component in the Coulomb law.

5.3 Performance

Table 2 shows that our method fits in well with the Projective dynamics algorithm. Indeed, compared to the native algorithm without

We do not need to modify the left-hand side of the global solve, we
and most follow-up papers. We have observed a speed gain.

tions on the

(a) $t = 0$s.

(b) $t = 0.4$s.

(c) Velocity of the center of mass.

(d) Height of the center of mass.

tions on the Sphere1 scenario.

contact, it only adds a small overhead when computing the right-
hand side of the global equation and locally updating contact forces
using our sorting algorithm (columns in orange). Additionally, as
we do not need to modify the left-hand side of the global solve, we
preserve the inherent speed of Projective dynamics.

Comparison with penalty contact forces. We have run Square1 by
computing contacts as penalty forces, similarly to [Bouaziz et al.
2014] and most follow-up papers. We have observed a speed gain
$g = \frac{\text{Bouaziz}}{\text{ours}} = 1.1$ brought by our approach, even though ours is
richer and more robust as it fully captures the Signorini-Coulomb
law in a semi-implicit way. This overhead in [Bouaziz et al. 2014]
is due to the Cholesky factorization which needs to be performed
at each global step, and eventually represents a cost of 21% of
the global step on average.

Comparison with Argus [Li et al. 2018]. Table 2 reports the aver-
age cost of Argus’s timesteps for Square1, Square3, and Arabesque
run with the same number of vertices and the same timestep values
used by our method, and without adaptivity. It turns out that our
method runs more than one order of magnitude faster, with a speed
gain$^1$ comprised between $\times 15$ and $\times 36$. We have noticed that the
Argus solver is especially penalized when many self-contacts are
involved (Square3 example), due to their handling through vertex
duplication and artificial pin constraints.

5.4 Limitation

Our method of course inherits limitations of Projective dynamics,
and in particular the lack of a simple rule to ensure convergence. In
order to obtain stable simulations, the user needs in a preliminary
step to adjust the number of iterations required, depending on the
mesh size and the material used.

Second and more importantly, our algorithm only considers vertex-
vertex contact, which can be insufficient for handling properly some
specific scenarios, such as cloth contacting an obstacle with corners
or sharp edges. However, treating a contact point that is not a node
is not straightforward. In such a case, the block lines of the matrix $J$
relating velocities of the contact points $u$ to the degrees of free-
dom $v$ do not only contain one rotation, but a linear combination
of rotations. Thus, per contact point, the system is not invertible as it is
with nodal contacts. Including vertex-face and edge-edge contact
in our framework hence remains an open direction of research.

Finally, our experiments on convergence suggest that the accuracy
of our method degrades as the variation of internal forces increases.
In the future we plan to investigate how to improve numerical
convergence in these cases.

6 CONCLUDING REMARKS

We have presented a simple method to introduce dry frictional con-
tact into the Projective dynamics framework in a robust yet cheap
way. Our technique preserves the global step Cholesky factoriza-
tion that is a keystone of the speed of the method, and only adds a
small overhead when assembling the equations and updating con-
tact forces. There are still many ways to improve the efficiency of
our method, such as mesh adaptivity [Narain et al. 2012], GPU im-
plementation [Wang 2015], and efficient detection collision scheme.
In future work we plan to build upon these orthogonal works in the
hope of reaching full interactivity of the approach.

ACKNOWLEDGMENTS

We would like to thank Jie Li and Rahul Narain for their help with the
Argus code and the analytical scenario, as well as the anonymous
reviewers for their useful comments. This work was supported in
part by the ERC grant GEM (StG-2014-639139).

$^1$With adaptivity enabled in Argus, the speed gain lies between $\times 6.5$ and $\times 8$.
