Abstract—**Virtual environments (VE) and haptic interfaces (HI) tend to be introduced as virtual prototyping tools to assess ergonomic features of workstations. These approaches are cost-effective and convenient since working directly on the Digital Mock-Up in a VE is preferable to constructing a physical mock-up in a Real Environment (RE). However it can be usable only if the ergonomic conclusions made from the VE are similar to the ones you would make in the real world. This study aims at evaluating the impact of visual and haptic renderings in terms of biomechanical fidelity for pick-and-place tasks. Fourteen subjects performed time-constrained pick-and-place tasks in RE and VE with a real and a virtual, haptic driven object at three different speeds. Motion of the hand and muscles activation of the upper limb were recorded. A questionnaire assessed subjectively discomfort and immersion. The results revealed significant differences between measured indicators in RE and VE and with real and virtual object. Objective and subjective measures indicated higher muscle activity and higher length of the hand trajectories in VE and with HI. Another important element is that no cross effect between haptic and visual rendering was reported. Theses results confirmed that such systems should be used with caution for ergonomics evaluation, especially when investigating postural and muscle quantities as discomfort indicators. The last contribution of the paper lies in an experimental setup easily replicable to asses more systematically the biomechanical fidelity of virtual environments for ergonomics purposes.**

I. INTRODUCTION

THE development of virtual reality headsets and glasses has been accelerated in the last few years, becoming popular in many applications. One of those applications is the virtual prototyping of workstations and products, that is a real asset in the industry [1], [2]. The interest of the use of virtual environment for applied ergonomics has been shown for more than twenty years [3]. More recently, studies have examined the use of virtual prototyping for the evaluation of ergonomics and human performance during the design phase [4]. Indeed, virtual prototyping is more cost-effective and convenient since creating and modifying a Digital Mock-Up (DMU) in a virtual environment (VE) is easier and less time-consuming than creating and modifying a physical one [5], [6]. The integration of physical risk factors assessment - ergonomics evaluation - in this prototyping has been recently introduced, showing interesting results for manual handling operations [3], [7], [8]. In those applications, the end-user - ideally the operator for which the design is realized, is immersed in a VR-based simulator and interacts with it as he would interact in the real world. One of the major features to be fulfilled to make such an

evaluation valuable is to guarantee that results and conclusions obtained in VE are similar to the ones you would obtain in the real world. Indeed, the usefulness of the results is deeply related to the level of fidelity of the simulator – the extent to which interactions in a VE are indistinguishable from interactions in a real environment (RE). Fidelity of VEs has been described in literature as a composite feature of three main dimensions: simulation, display and interaction fidelity [9], [10], to which we can add a transverse dimension called biomechanical fidelity, or biofidelity - the degree of similarity between motions, forces, and tasks realized in RE and VE at a biomechanical level (the level used to assess physical risk factors in ergonomics) [11]. A high biomechanical fidelity rate would ensure that the conclusions of studies using VE may be valid for the real world. Indeed it explains the idea that biomechanical quantities are consistent between a real and an equivalent virtual activity.

Biomechanical fidelity assessments were mostly conducted on tasks involving low levels of interaction or force, enabling the use of tracked devices with no haptic feedback to interact with the virtual scene [12], [13], [14], [15]. However, for more complex interactions and tasks involving moderate to high level of forces, the interaction must be rendered through haptic interfaces (HI). The current study aimed at assessing the biomechanical fidelity for pick-and-place tasks realized in RE and VE with or without haptic interaction.

A few studies investigated the fidelity of a virtual scene involving haptic rendering for ergonomics purposes. First, in [16], sorting tasks with low masses (wooden pieces) were assessed in real, virtual, and virtual plus force feedback conditions - realized with a 6-DOF haptic device based on impedance control (Virtuose 6D, Haption SA). Postures and muscle activities were assessed and compared between environments and between subjects, showing that the haptic device limited the interaction fidelity, with a poor level of similarity between joint angle trajectories and muscle activities recorded in RE and VE. The main reason behind this result was the relative ineffectiveness of the mechanical structure of the haptic device to enable complex manipulations involving large range of motions, more than the control scheme applied to it. Second, in [17] was proposed an approach in which was gradually evaluated the impact of a) the virtual head-set b) the presence of an haptic device c) the haptic rendering for assembly tasks. They used the HUG [18], consisting of two torque-controlled 6-dofs haptic robots. Three tasks were investigated: frontal and side insertion, and railing. Results showed that all synthetic interactions increased the time to

complete the tasks. The force feedback generated by the HI was always bigger than the real interaction. The muscle activity was higher with the synthetic interactions than with the real ones, especially when interacting with the haptic device. The ratings of subjective overall, contact and manipulation realism and the perception of mental and physical workloads were negatively affected by each synthetic interaction. These results clearly mitigate the usefulness of such approaches and make the VE not realistic enough to be used as it is.

The approach of the current study is similar to those presented in the previous paragraph. We developed an original setup, enabling to separate the effect of visual and haptic renderings in the scene in order to investigate individual and combined effects of those modes of immersion and interaction on the biomechanical behavior of the subject during the task. The study focused particularly on the mixed effects of the renderings on the biomechanical fidelity of the system to simulate pick-and-place tasks. The paper is first presenting the experimental protocol and the statistical processing, and then presents and discusses the results with regard to the aforementioned objectives.

II. MATERIALS AND METHODS

In the present study, we designed and conducted experiments on simulated pick-and-place tasks with real or virtual visual feedback (VF) and with two levels of haptic interaction (HIn), a real interaction with a real object and a synthetic interaction with a commercial HI, comparing several indicators based on biomechanical quantities.

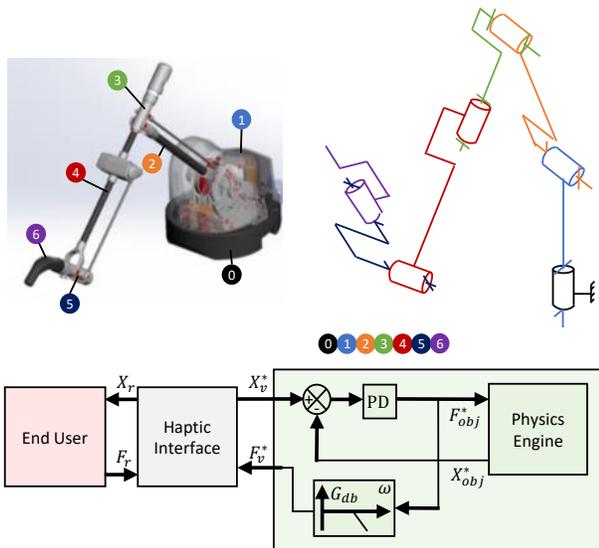

Fig. 1. Top left : Virtuose6D 3D mock-up. Top right : Kinematic scheme of the HI. Bottom : Detailed haptic interaction. End-user interacted with the haptic display by moving the end-effector X_r. The position of each joint X_v^* was captured, digitalized and sent to the VE. It was coupled to the object scene through a virtual spring-damper because of the admittance control of Rigidbody, the physics engine used. The resulting force F_v^* was low-pass filtered and sent to the HI and used to apply to the end-effector as the force feedback.

A. Subjects

Fourteen subjects, twelve males and two females, participated in this study after giving their informed consent. They were relatively experienced in VE (average experience of 3.6 ± 2.0 on a seven-point scale) and nearly novice with HI (average experience of 2.0 ± 1.1 on a seven-point scale). Mean subject age was 25.6 ± 9.3 y.o. They were all right-handed and none of them declared musculoskeletal disorder within the last six months. The study was approved by the Inria national ethics committee (COERLE 2017-13).

B. Task

The chosen task was a simplified pick-and-place task (Fig. 2) that can be found in industrial situations. It consisted in moving (back and forth) a $470g$ object between two target zones placed on a table and spaced $36.4cm$ apart. Objects handle was a 3D printed reproduction of the HI handle in order to avoid any change in the grip. Each target zone included a rectangle and a circle of the size of the object base and handle. The subjects were sitting on a chair in front of the table and placed in order to have their arm along their body and the elbow flexed at 90 degrees when the object was on the nearest target. A cylindrical obstacle was placed between these two zones.

During a trial, the subject performed five back and forth motions with the object at each of the three following speed rates: slow, medium, and fast (1.5, 1 and 0.7 second to achieve a motion from one target to another respectively). It corresponded to 10 pick-and-place repetitions per speed. A pause of 1 second was respected between each repetition and a pause of 5 seconds was respected between each change of pace leading to a total duration of 69 seconds. A metronome indicated the pace to be followed by the subject. Before the start, the subject had two training trials with real visual feedback/object and virtual visual feedback/object to get used to the different rhythms to be followed and to the use of the head-mounted display (HMD) and the haptic interface. The trials were performed twice per visual feedback (VF)/haptic interaction (HIn) modes combination : interaction with real object without HMD, interaction with real object with wearing HMD, interaction with HI without wearing HMD and interaction with HI with wearing HMD. Figure 2 shows the four different combinations of VF and HIn. In summary, the subject had to perform eight sequences of fifteen back and forth motions (30 pick-and-place repetitions) for a total of 240 pick-and-place repetitions.

During the experiment, the order of the different combinations of VF and HIn was randomized and the modes of VF and HIn were announced before each trial. However speed conditions were systematically realized from the slowest to the fastest for all trials.

C. Setup

1) Virtual environment: The VE was designed and implemented in Unity3D 5.6.1[1] (Unity technologies™) in order to
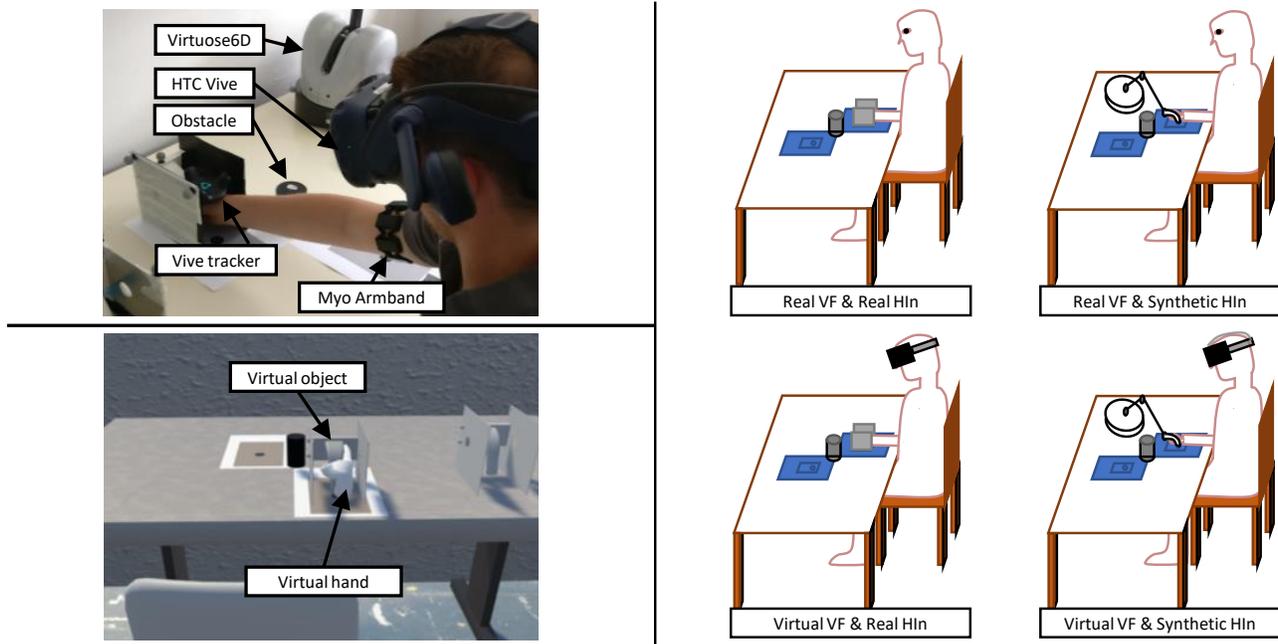

[1]https://unity.com/

Fig. 2. Top left: Experimental setup with two targets for pick-and-place tasks. A cylindrical obstacle $8cm$ in diameter and $10cm$ high was placed between the targets. The HI (Virtuose6D) was placed close by so that the movement was within its range of accessibility. The subject was equipped with a Vive tracker to record the position and orientation of his hand and with a myo bracelet to record the electromyographic activity of his arm. Finally, the subject was equipped with an HTC Vive Pro helmet during the virtual immersion where the virtual scene was projected. Bottom left: This virtual scene included the same elements as the real scene except for the HI with the addition of a virtual hand collocated thanks to the Vive Tracker. Right: Illustration of the four combinations of immersion/interaction modes.

mimic the RE - except the representation of the HI. VE was used for both the virtual visual feedback and to control HI. The 3D representation of the manipulated object was derived from the digital mock-up used to fabricate the real one. The physics of the scene was simulated using the Unity module Rigidbody. Notably, the friction between the object and the table has been implemented as a Coulomb friction with usual coefficients of wood/steel friction: 0.5 static friction and 0.5 dynamic friction. An head mounted display (HMD) HTC Vive pro[2] (HTC[TM]) was used to display the VE to the subject. The SteamVR plugin has been used to ensure compatibility between Unity3D and the HTC Vive pro. The standard calibration protocol proposed by the software SteamVR was set before each experiment. It consisted in the set-up of the equipment (HMD, controllers and Vive Tracker), the set up of the desk as the floor to ensure that the virtual desk and the real one were parallel and at the same height and the set up of the reachable area of the subject. Finally, to ensure the collocation of the two targets, We performed a rigid solid calibration with three degrees of freedom (two horizontal translations and the vertical rotation) by putting consequently the tracker at the bottom right of the right target and at the top left of the left target.

2) Haptic interaction: Synthetic haptic interaction was realized with a Virtuose 6D High Force[3] (Haption[TM]), a six degree of freedom impedance HI providing a continuous force of $30N$ and a continuous torque of $1.4N.m$. As the Rigidbody physics engine is in admittance mode, the coupling (see Fig. 1) between the HI and the physics engine was provided by a

virtual spring-damper of $250N.m^{-1}$ stiffness and $15N.s.m^{-1}$ damping. This setting was obtained from a previous study [19] and a pilot experiment. This coupling and the physics engine were running at $250Hz$ due to computing power limitations.

D. Recordings

Muscle activity of the upper arm was recorded with a Myo armband (Thalmic Labs[TM]). Elastic armband Myo is a low cost electromyographic (EMG) sensor system consisting in 8 EMG sensors sampled at 200Hz. It was placed one-third of the distance between the lateral epicondyle and the acromion from the coronoid fossa (see Fig. 3).
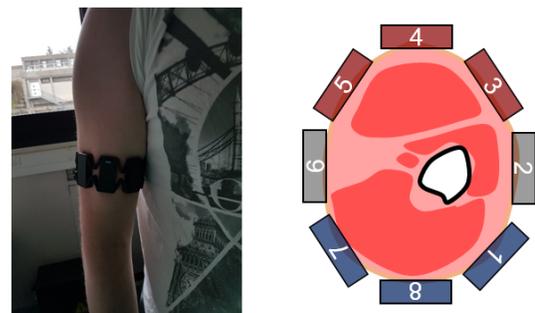

Fig. 3. Myo Armband position on subject upper arm (left) and sectional view (right).The Myo Armband, composed of 8 EMG electrode pairs, was placed on the arm of the subject. Electrode pair 4 served as reference and was always placed on the biceps brachii. The averaged muscle activation of biceps brachii (AMAb) was obtained by averaging the measure from electrodes pairs 3-4-5 (red electrode pairs), as well as the averaged muscle activation of triceps brachii (AMAt) with the electrode pairs 7-8-1 (blue electrode pairs).

[2]https://vive.com/
[3]https://haption.com/

Motion of the hand was captured with a HTC Vive tracker set on the back of the hand in the middle of the second and third metacarpals. The position of the hand recorded by the tracker was sampled at $60Hz$. The accuracy of such trackers has a standard deviation of 5mm [20].

At the end of the experiment, subjects answered a questionnaire including items about haptic interaction and items from the Witmer-Singer [21] presence questionnaire, on a 7 points Likert-scale [22].

E. Indicators

1) Averaged Muscle Activations (AMA): Averaged Muscle Activations of biceps brachii (AMAb) and of triceps brachii (AMAt) were the averaged measures of the 3 electrode pairs of the Myo armband placed on the biceps and the 3 placed on the triceps (see Fig. 3). AMAb and AMAt gave a fairly good overview of the elbow flexor and extensor muscles activity during the task to compare the different conditions. To compute these indicators, the electrodes signals were detrended and filtered with a root mean square filter with a window set at $200ms$ according to [23]. These filtered signals were averaged for each pick-and-place repetition to obtain AMAb and AMAt per repetition. The AMAb and AMAt where then averaged per condition.

2) Hand motion: To estimate the spatial variability of the pick-and-place tasks among repetitions and conditions, the average distance of all trajectories to the median trajectory plane (APD) was studied. The median trajectory plane was defined in a least-squares sense among all repetitions of a given condition. Spatial variability is the component of the motor control variability observable in the task space, and it is relevant to compare this variability among conditions to understand how controlled is the motion performed. Indeed, this variability will be impacted by key control processes of the task realization - planning, correction for example, as well as with the familiarity of the subject with the task and the environment [24], [16], [25], [15]. In this study, APD was supposed to be a relevant metrics of this variability.

The total path length (TL) of the hand trajectory during each trial was calculated from a linear interpolation between the positions recovered by the HTC vive tracker projected in the average plane during a repetition. TL was supposed to be representative of the energy expense associated to the task (a shorter path meaning a lower energy expense). TL was averaged per condition.

The average distance (AD) between the starting and ending positions of the object on the work plane and the average avoidance height (AAH) were computed per condition, by averaging these values among repetitions. This indicator was particularly interesting to assess the perceptive differences between RE and VE.

The trajectory and three indicators - APD, TL and AD - are represented in Fig. 4.

Finally, the average maximum speed (AMS) was calculated. The position of the hand was filtered using a low pass filter with a cutoff frequency of 10Hz to suppress noise due to the accuracy of the tracker. This filtered position was numerically differentiated to compute the speed of the hand during the task. AMS was averaged per condition. It was supposed to be a relevant measure of the effectiveness with which the task was performed (the higher the speed was, the higher the task was effective).

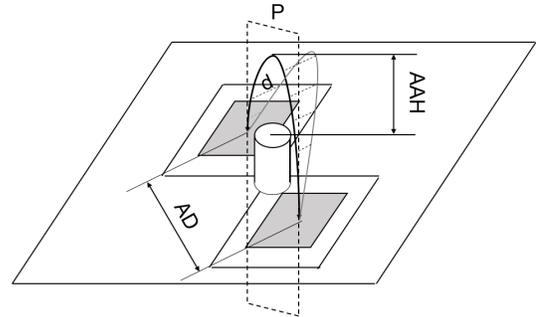

Fig. 4. Trajectory of one repetition (gray line) projected on the median plane P obtained from the 10 repetitions -5 back and forth - of a given trial (black line). The average distance to the median plane (APD) was calculated from the average of each distance (d). The average distance (AD) and the average avoidance height (AAH) are also represented.

F. Statistics

Visual feedback type (set to real and virtual), haptic interaction type (set to real and synthetic) and speed (set to slow, medium or fast) were introduced as factors in a full factorial repeated measure of variance (ANOVA) of the dependent variables, which were the objective indicators (AMAb, AMAt, APD, TL, AD, AAH, and AMS). The probability value was adjusted through a Greenhouse-Geisser sphericity correction. The level of confidence was set to $p < 0.05$. A post hoc Tukey honestly significant difference (HSD) test was performed on the significant factors identified with the ANOVA.

III. RESULTS

A. Objective indicators

1) AMAs: According to Table I, AMAb - corresponding to the main muscles involved in the task realization - increased with the speed (+17% from low to medium; +14% from medium to high). In addition, AMAb was higher during virtual visual feedback (+6%) and synthetic haptic interaction (+5%), with regard to real conditions.

AMAt increased with virtual visual feedback (+36%) and speed (+11% from low to medium; +24% from medium to high), corresponding to higher muscle co-contraction during the task.

2) Hand motion: APD did not depend on the different factors and mean APD was $6 \pm 6mm$.

TL depended significantly on the level of immersion, interaction and speed. TL decreased with speed (-5% from low to medium; -4% from medium to high) and synthetic haptic interaction (-11%), but it increased with virtual visual feedback (+5%).

AD depended only on the speed, decreasing as the speed increased (-3% from low to medium; -11% from medium to high). At slow speed, AD, whether in immersion and

interaction types, was close to the physical distance between targets ($36.1cm$ for AD vs. $36.4cm$ for the physical distance).

AAH depended significantly on the type of interaction and especially on the type of immersion and speed. AAH was lower during synthetic haptic interaction (-23%) and higher speed (-8% from low to medium; -22% from medium to high), however it was higher in virtual visual feedback (+15%).

AMS depended significantly on the type of interaction, immersion and speed. AMS increased with speed (+3% from low to medium; +9% from medium to high) and virtual visual feedback (+3%), but decreased in synthetic haptic interaction (-9%).

B. Subjective results

Only relevant subjective results were reported here, among the complete questionnaire proposed to the subjects. Results showed that the task specifications were adapted to the HI used: its mechanical structure did not disturb the subjects in their motion (2.79 ± 1.72). Moreover, the force feedback seemed realistic (5.07 ± 1.00) and the feeling of contact between the manipulated object and its environment did not perturb the subjects (2.71 ± 1.59). However the manipulation of the object through the HI seemed to be more difficult than the real manipulation (5.00 ± 0.68). The collocation of the elements on the scene seemed to be quite satisfying (hand: 5.00 ± 1.47, real object: 4.64 ± 1.65 and virtual object (haptic driven): 5.93 ± 1.07) and subjects found that the virtual scene rendering was very good (5.79 ± 1.12) with no perceptible delay (1.43 ± 0.65). Overall, subjects evaluated the virtual immersion to a satisfying level of presence. Finally, they preferred to have virtual visual feedback when interacting with the haptic feedback (2.93 ± 1.73; 1-Virtual 7-Real visual feedback) and preferred to have real visual feedback when interacting with the real object (5.79 ± 1.63).

IV. DISCUSSION

Overall the results show significant differences between the conditions of the current study in terms of muscle activation,

trajectory and kinematics. As expected synthetic haptic interaction and virtual visual feedback altered significantly the pick-and-place task. The increase of the speed condition led to an increase in inertial effects, therefore the force required to move the object was greater. Furthermore, according to [26], [27], to perform a precise task at a higher rate it is necessary to increase the stiffness of the joints by increasing the muscle co-contraction. These observations explain the increase in activation for both muscle groups with regard to speed. On the other hand, the increase in speed decreased the accuracy and shortened the trajectory, reducing the average distance between starting and ending positions and the avoidance height [28]. Subjects may had issues to perform the task at higher speeds, resulting in narrower trajectories as shown by the decrease of TL accompanying the increase of AMs.

The use of a HI resulted in an increase in muscle activity of the biceps, which is the one of the main muscles involved in the task, assuming that the end-user must make an effort to move both the virtual object and the HI handle [17]. On can suppose that the effects of inertia and friction of the HI were added to the effects of inertia of the object. The subjective questionnaire evidenced that the feeling of effort during the task was more important when using the HI, as already explained in [19] for low masses manipulations. On the other hand, the synthetic haptic interaction led to a decrease in the AAH and thus in the total length of the trajectory TL. This could be explained on the one hand by the fact that the object has an increased visual burden compared to the HI handle. However, there is no significant difference between synthetic haptic interaction with real and virtual visual feedback, depreciating this assumption. In addition, the subject inexperience with HI can have led in hampering in using its entire accessible space. On the other hand, the increase of the effort inherent to the use of the HI may have caused the changes observed in the trajectory. Furthermore, this can explain the lower maximum speed with HI. The virtual object to handle was designed from the real object and mass properties were applied from those of the - estimated - real object. Even if we reported the same order of amplitude for

real and virtual forces arising from this object manipulation in [19], differences in mass properties between real and virtual object may have an impact on the behavior of the subject.

Finally, virtual visual feedback led to an increase in trajectory length, with a significant increase in obstacle avoidance height. This may be due to the error of perception of space in virtual reality. According to [29], [30], [31], VE distance perception is compressed so subjects tend to increase the safety margin with the object. Additionally, no hand-eye calibration was followed in the setup [32], that may have diminished the distortion by applying corrective rules to the display. There is a greater increase in triceps activity compared to biceps activity than in the effect of speed. There is therefore an increase mainly in the co-contraction of these muscles during virtual visual feedback, that can be probably explained by a unfamiliarity with the environment and therefore an increase of trajectory control by stiffening the arm [14].

Surprisingly, no significant statistical interaction was found between immersion and interaction renderings for all the indicators. This is interesting and opens the door to study the effect of visual and haptic interaction separately for such tasks. However, subjects reported a preference to have all in virtual or all in real to perform the task, meaning that hybrid setups may be too unfamiliar to be properly handled by the user to perform this kind of task.

Another interesting result is the APD one, showing no significant change in spatial variability from one setup to one other. Indeed, authors assumed that this metric may have been influenced by conditions, especially with the haptic interaction with regard to the real object. The unfamiliarity of the subject with haptics should have led to an increase in spatial variability when performing the task. The subjects seemingly preferred to adopt conservative strategies in order to perform the task instead of keeping similar speed and trajectory between the two conditions. In other words, they changed the way they performed the task to adapt to the HI, that is also a strong bias in assessing biomechanical quantities in such conditions. The adaptation of the subject to the device change drastically the macro (task) and micro (muscle) motor control for similar conditions. Therefore, the similarity of the biomechanical quantities between RE and VE can not be ensured. In addition, only the trajectory of the hand was recorded. It would be necessary to capture the whole body motion of the subject in order to study in more detail the biomechanical fidelity of this task and thus its similarity with the task in real world. Indeed we cannot see if there is any compensation strategy explaining changes in the trajectory of the hand.

As shown in Fig. 5, and as described above, the muscle activation strategy was different between the real and simulated task. Indeed the activation of the biceps was more important at the beginning and end of the movement during the real task, whereas during the simulated task it was more important either at the end of the movement during the outward phase or at the beginning of the movement during the return phase. Moreover, there was a disparity between the rest phases after the outward and return phases concerning the activation of the biceps and triceps. During the rest phase on the farthest target, only the activation of the triceps increased in the case of the real task

whereas the activation of the triceps and biceps increased in the case of the simulated task, that is also explained by a higher limb stiffness with the synthetic haptic rendering. Finally the speed curves seemed to be typical bell-shaped curves that are classically found for pointing tasks, in both conditions [33]. This is the main limit of the current study: these conclusions can only apply on pick-and-place setups and tasks, that are really similar to pointing tasks. The task was voluntary simplified and the timing was clearly controlled, that may certainly have led to an adaptation of the subject to the task.

This study exhibits other limitations. Firstly, the number of subjects is quite limited and the population is not representative of people concerned by such an application, since the majority of subjects were recruited in our laboratory. Secondly, the choice to constrain time by sound signals probably led to a learning effect to follow the rhythm during the experiment, even if each subject had two training trials beforehand. The number of repetitions being quite large (240 pick-and-place movements), the effect of learning was supposedly limited. The, this study observed only the muscle activity of the flexors and extensors of the elbow as well as the kinematics of the hand without taking into account the posture and global activity of the subject, that may have revealed compensatory strategies. Last, as mentioned before, hand-eye coordination and a better estimation of mass properties of the virtual object may also have diminish the differences between real and synthetic modalities.

To sum up, for applications requiring a high level of biomechanical fidelity, such as industrial workstation ergonomics assessment, the study confirms that virtual reality and HI are subject to caution without improving the rendering. Indeed, in addition to decreasing the end user's experience, these haptic interaction and immersion modes bring a bias of the order of 10% to 15% concerning muscle activity, trajectory and kinematics. Few studies considered the improvement of haptic rendering from a biomechanical point of view for object manipulation [19], [34], [35], in contrast to methods for improving contact and shock rendering. The main drawback of HI in the case of object manipulation is the increased force required to move the object by introducing friction and additional inertia. However, rendering algorithms for haptic interaction have been studied from a system point of view. Most of these methods are based on the addition of one or more feedback loops in the control structure of the HI. These feedback loops are mostly sensor-based [36] or model-based [37]. Biomechanical fidelity may be improved by using one of these methods instead of the classical control scheme proposed in the current study. Finally, many studies have been done on the effects of virtual visual feedback for object manipulation and methods of improvement have been proposed with encouraging results [38], [39].

V. CONCLUSION

Virtual immersion with the use of haptic interface has shown many applications such as professional training [40] and ergonomics [5]. These technologies have moderate performance.
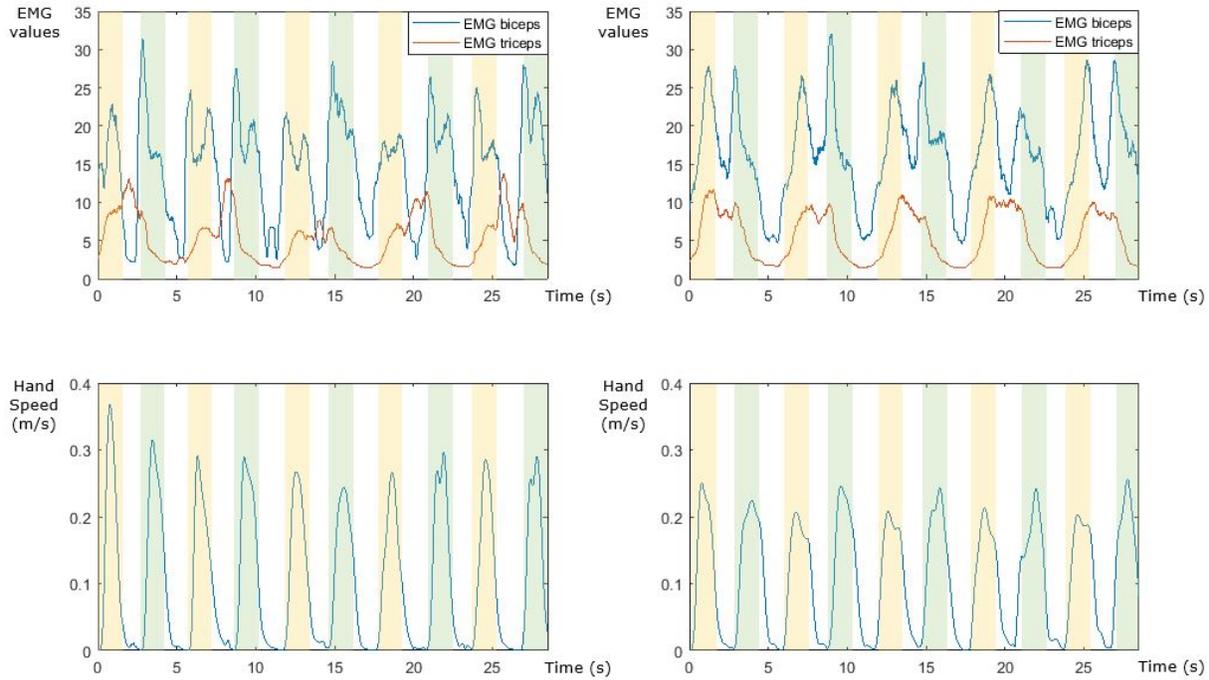

Fig. 5. Averaged EMG data (top) and hand speed (bottom) for real task (real visual feedback and haptic interaction) (left) and for virtual task (virtual visual feed back and synthetic haptic interaction) (right) at low speed. Yellow zone: outward phase, green zone: return phase, white zone: rest phase.

The aim of this study was to evaluate individual effects and cross-effects of synthetic haptic interaction and virtual visual feedback on the biomechanical fidelity of simulated pick-and-place tasks performed at different speeds. EMG signals and hand motion were used as objective indicators, and a questionnaire was used to gather subjective results. The different conditions caused significant differences in the variables. In particular, the synthetic haptic interaction exhibited a higher motor muscle activation without increasing co-contraction, the decrease in the length of the trajectory and the decrease in the maximum velocity of the hand. The significant differences were due notably to the non-transparency of HI, which exhibits a higher force feedback than the one calculated by the physics engine because of its mechanical behavior (inertia of its parts, frictions of its joints). Moreover, these effects were particularly important for low masses manipulations. On the other hand, virtual visual feedback resulted in an increase in co-contraction and a modification of the trajectory which would be mainly due to the compression of distance perception.

It is well known that such VR-based systems should be used with caution for ergonomics purposes. Regarding this observation, we developed an original setup, enabling to separate the effect of visual and haptic renderings in the scene. So, an important result of our study is that there was no cross-effect between haptic interaction and immersion enabling to study separately the mode of immersion and interaction for this kind of task, which are abundant in the literature. It opens the door to many dedicated setups to evaluate specific rendering modalities of fidelity fort ergonomics purposes. Moreover, the study enabled to develop specific indicators and methodologies able to provide a fair idea of the biomechanical fidelity of a simulated task from a set of easily accessible quantities. Such an approach should be systematized as a standardization of biomechanical fidelity assessment for ergonomics purposes.

The focus on simple tasks as pick-and-place ones makes the results of the study easily replicable and useful for many industrial tasks. However, limitations of this study leads to the necessity of future works focused on more challenging tasks, involving higher force exertion levels and more complex manipulations with more representative population and numerous cohort. This may require additional developments in haptics rendering control schemes, in order to reach acceptable levels of biomechanical fidelity for such applications.
