Key Points:

- A physically relevant stochastic parametrization of the shallow water model is introduced
- The proposed stochastic model conserves the total energy and motivates a structure preserving discretization
- This stochastic parametrization provides a good trade-off between model error representation and ensemble spread

Corresponding author: Rüdiger Brecht, rbrecht@mun.ca

Abstract

We introduce a physically relevant stochastic representation of the rotating shallow water equations. The derivation relies mainly on a stochastic transport principle and on a decomposition of the fluid flow into a large-scale component and a noise term that models the unresolved flow components. As for the classical (deterministic) system, this scheme, referred to as modelling under location uncertainty (LU), conserves the global energy of any realization and provides the possibility to generate an ensemble of physically relevant random simulations with a good trade-off between the model error representation and the ensemble's spread. To maintain numerically the energy conservation feature, we combine an energy (in space) preserving discretization of the underlying deterministic model with approximations of the stochastic terms that are based on standard finite volume/difference operators. The LU derivation, built from the very same conservation principles as the usual geophysical models, together with the numerical scheme proposed can be directly used in existing dynamical cores of global numerical weather prediction models. The capabilities of the proposed framework is demonstrated for an inviscid test case on the f-plane and for a barotropically unstable jet on the sphere.

Plain Language Summary

The motion of geophysical fluids on the globe needs to be modelled to get insights of tomorrow's weather. These forecasts must be precise enough while remaining computationally affordable. Ideally they should enable to estimate likely scenarios through an ensemble of physically relevant realizations, built from an accurate handling of the model errors that are inescapably introduced due to physical or numerical approximations. To address these issues, we advocate the use of a stochastic framework to represent the action of the many unresolved fast/small-scale processes on the resolved flow component. The derivation of the stochastic system, based on the usual conservation laws, is presented in detail and simulated with an adapted structure preserving numerical model to maintain numerically the nice properties of the stochastic setting inherited from a transport principle, namely: mass and energy conservation. The versatile nature of the stochastic derivation as well as of the proposed numerical scheme makes this framework suitable for existing dynamical cores of global numerical weather prediction models. Numerical results illustrate the energy conservation of the numerical model and the accuracy of large-scale stochastic simulations when compared to corresponding deterministic ones. The ability of the random dynamical system to represent model errors is also shown.

1 Introduction

Numerical simulations of the Earth's atmosphere and ocean play an important role in developing our understanding of weather forecasting. A major focus lies in determining the large-scale flow correctly, which is strongly related to the parameterizations of sub-grid processes (Frederiksen, O'Kane, & Zidikheri, 2013). The non-linear and non-local nature of the dynamics of geophysical fluid flows make the large-scale flow structures interact with the smaller components. Solving the Kolmogorov scales (Pope, 2000) of geophysical flows is today, and likely for a foreseeable future, completely out of reach. This is due, in the first place, to the formidable computational expense that would be necessary, but also to the complexity of the many fine-scale physical or bio-chemical processes involved. Truncating the fine scales and simply ignoring their actions is highly detrimental to a reliable simulation of the large-scale components of the flow. Yet, an accurate modelling of the fine-scale processes' effects is an excruciatingly difficult task and the idea of a stochastic modelling has strongly attracted the geophysical community since the seminal works of (Hasselmann, 1976) and (Leith, 1975). For several years, this interest has been strongly strengthened with the emergence of ensemble methods for probabilistic forecasting and data assimilation issues (Berner & Coauthors, 2017; C. E. Franzke,

66 O’Kane, Berner, Williams, & Lucarini, 2015; Gottwald, Crommelin, & Franzke, 2017;
 67 Majda, Franzke, & Khouider, 2008; Palmer & Williams, 2008; Slingo & Palmer, 2011).

68 The schemes proposed so far rely on very different methodological concepts. Multiplicative random forcing and randomization of parameters based on early turbulence
 69 studies on energy backscattering (Leith, 1990; Mason & Thomson, 1992) have been proposed (Buizza, Miller, & Palmer, 1999; Porta Mana & Zanna, 2014; Shutts, 2005). The
 70 ad hoc nature of these schemes makes a systematic stochastic derivation of any flow dynamical model or configuration difficult. In addition, the absence of an explicit energy
 71 balance of the noise term leads to an uncontrolled increase of variance that is potentially problematic. They consequently require a proper tuning of the large-scale sub-grid model
 72 and of the noise amplitude to stabilize the system. The subgrid model is, however, not related to the noise term and the amplitude of the perturbations to apply is also difficult
 73 to specify on physical grounds. More importantly, even for low noise, an arbitrary random perturbation defined outside of the physical principles on which the system has
 74 been built upon may lead to strongly erroneous probability density functions of the system’s dynamics (Chapron, Dérian, Mémin, & Resseguier, 2018). Other schemes based
 75 on an averaging and homogenization theory have been proposed (C. Franzke, Majda, & Vanden-Eijnden, 2006; C. E. Franzke & Majda, 2006) in the wake of (Majda, Timofeyev,
 76 & Eijnden, 1999) and extended through the Mori-Zwanzig formalism (see the review (Gottwald et al., 2017) and references therein). Those techniques are well suited for the design of
 77 stochastic reduced order systems.
 78

87 In this study, we propose to stick to a specific stochastic model, called modelling under *Location Uncertainty* (LU) derived by (Mémin, 2014), which emerges from a decomposition
 88 of the Lagrangian velocity into a smooth-in-time drift and a highly oscillating random term. Such a slow/fast or smooth/oscillating decomposition is reminiscent to the Lagrangian
 89 decomposition introduced in the seminal work of (Andrews & McIntyre, 1978), which is currently used for surface or internal waves studies (Kafiabad, Vanneste,
 90 & Young, 2021; Salmon, 2013; Young & Jelloul, 1997; Xie & Vanneste, 2015). A similar random decomposition is also at the center of the variational stochastic framework
 91 of (Holm, 2015). Like our setting this latter approach applies in a broader context and not only to wave solutions. Both frameworks rely on a stochastic transport principle, with
 92 (Holm, 2015) dedicated to Hamiltonian dynamical systems and defined from a circulation preserving constrained variational formulation, while (Mémin, 2014) is general and
 93 built upon classical physical conservation laws.
 94

100 This stochastic transport principle has been used as a fundamental tool to derive stochastic representations of large-scale geophysical dynamics (Bauer, Chandramouli, Chapron,
 101 Li, & Mémin, 2020; Bauer, Chandramouli, Li, & Mémin, 2020; Chapron et al., 2018; Resseguier, Mémin, & Chapron, 2017c, 2017b, 2017a) or to define large eddy simulation models of
 102 turbulent flows (Chandramouli, Memin, & Heitz, 2020; Kadri Harouna & Mémin, 2017). The LU framework relies on a stochastic representation of the Reynolds transport theorem
 103 (Kadri Harouna & Mémin, 2017; Mémin, 2014) which introduces naturally meaningful terms for turbulence studies.
 104

108 It gathers a multiplicative random advection which is responsible for an energy backscattering, a subgrid diffusion operator describing the mixing of the large-scale flow component
 109 by the small-scale random component, and an effective advection which is attached to the small scales spatial inhomogeneity. This latter term has been shown to be reminiscent
 110 of a generalized Stokes drift component, hence designated as Itô-Stokes drift (Bauer, Chandramouli, Chapron, et al., 2020). Backscattering and diffusion are energetically in
 111 balance which leads hence to global energy conservation.
 112

115 Recently, the LU formulation was shown to perform very well for oceanic quasi-geostrophic flow models (Resseguier et al., 2017b, 2017a; Bauer, Chandramouli, Chapron,
 116 et al., 2020; Bauer, Chandramouli, Li, & Mémin, 2020). It was found to be more accu-
 117

118 rate in predicting the extreme events, in diagnosing the frontogenesis and filamentogene-
 119 nesis, in structuring the large-scale flow and in reproducing long-terms statistics. Besides,
 120 for a LU version of the Lorentz-63 model, derived from a Rayleigh-Bénard convection
 121 in the very same way as the original model (Berge, Pomeau, & Vidal, 1987; Lorenz, 1963),
 122 it has been demonstrated that the LU setting was more effective in exploring the range
 123 of the strange attractor compared to classical models as well as to stochastic models built
 124 with ad hoc multiplicative forcings (Chapron et al., 2018).

125 In this work, the performance of the LU representation is assessed for the numerical
 126 simulation of the rotating shallow water (RSW) system, which can be considered as
 127 the first step towards developing global random numerical weather prediction and cli-
 128 mate models. In particular, this is the first time that the LU formulation is implemented
 129 for the dynamics evolving on the sphere. The global energy conservation of the RSW-
 130 LU system for any realization, which is analytically demonstrated here, is a strong as-
 131 set of the approach and this invariant feature should be numerically conserved as closely
 132 as possible. Global energy conservation is especially important for long-term climatic sim-
 133 ulations. However, classical purely damping parameterizations do not take into account
 134 energy and momentum fluxes from the unresolved to the resolved scales. In climatic mod-
 135 els, this is believed to be a source of important biases (Gugole & Franzke, 2019).

136 Hence, we propose to combine the discrete variational integrator for RSW fluids
 137 as introduced in (Bauer & Gay-Balmaz, 2019a) and (Brecht, Bauer, Bihlo, Gay-Balmaz,
 138 & MacLachlan, 2019) with the numerical LU setting in order to maintain this conser-
 139 vation property as well as all the transport invariants. The benefit of the proposed method
 140 that relies on a modular combination of a variational integrator with a (potentially dif-
 141 ferent) discretization of the LU formulation is that it should be directly applicable to ex-
 142 isting dynamical cores of numerical weather prediction models.

143 The derivation of the variational integrator is based on the variational discretiza-
 144 tion framework introduced by (Pavlov et al., 2011) for incompressible fluids, expanded
 145 by (Gawlik, Mullen, Pavlov, Marsden, & Desbrun, 2011) to incompressible fluids with
 146 advected quantities. In various papers, this framework has been further extended, for
 147 instance (Desbrun, Gawlik, Gay-Balmaz, & Zeitlin, 2014) incorporated rotating and strat-
 148 ified fluids of atmospheric and oceanic dynamics and (Bauer & Gay-Balmaz, 2019b) in-
 149 troduced soundproof approximations of the Euler equations. Variational integrators are
 150 designed by first discretizing the given Lagrangian, and then by deriving a discrete sys-
 151 tem of associated Euler-Lagrange equations from the discretized Lagrangian (see (Marsden
 152 & West, 2001)).

153 The advantage of this approach is that the resulting discrete system inherits sev-
 154 eral important properties of the underlying continuous system, notably a discrete ver-
 155 sion of Noether’s theorem that guarantees the preservation of conserved quantities as-
 156 sociated to the symmetries of the discrete Lagrangian (see (Hairer, Lubich, & Wanner,
 157 2006)). Variational integrators also exhibit superior long-term stability properties, cf.
 158 e.g. (Leimkuhler & Reich, 2004). Therefore, they typically outperform traditional in-
 159 tegrators if one is interested in long-time integration or the statistical properties of a given
 160 dynamical system. Our choice for an energy preserving rather than an enstrophy con-
 161 serving scheme is based on the following considerations. As shown in (Bauer, Chandramouli,
 162 Li, & Mémin, 2020) for stochastic barotropic quasi-geostrophic models, using an energy
 163 conserving scheme for long-term predictions yields better results than using an enstro-
 164 phy conserving one. Besides, because of the direct cascade of enstrophy to high wave num-
 165 bers, often stabilization through enstrophy dissipation is introduced, even in initially en-
 166 strophy conserving schemes, cf. (Bonaventura & Ringler, 2005; McRae & Cotter, 2014;
 167 Ringler & Randall, 2002).

168 Apart from taking into account the unresolved processes, it is paramount in prob-
 169 abilistic ensemble forecasting to model the uncertainties along time (Resseguier et al.,

2020). In particular, operational ensemble data assimilation methods rely classically on random perturbations of the initial conditions (PIC) together with an artificially carefully inflated variance (Anderson & Anderson, 1999) to increase the otherwise deficient ensemble forecasts' spread (Gottwald & Harlim, 2013; C. E. Franzke et al., 2015). Such inflation has the side effect of augmenting also the representation error of the ensemble members. In the present work, we compare the reliability of the ensemble spread of such a PIC model with our RSW-LU system, under the same noise amplitude, and show that the LU strategy yields a good trade-off between model error representation and ensemble spread.

The remainder of this paper is structured as follows. Section 2 describes the basic principles of the derivation of the rotating shallow water system in the LU formulation. Section 3 explains the numerical discretization of the stochastic dynamical system. Section 4 discusses the numerical results for an inviscid test case with homogeneous noise and a viscous test case with heterogeneous noise. In Section 5 we draw some conclusions and provide an outlook for future work. In the Appendices we demonstrate the energy conservation of the RSW-LU system, review some parameterizations of the noise and describe the discretization of the stochastic terms.

2 Rotating shallow water equations under location uncertainty

In this section, we first review the LU representation introduced by (Mémín, 2014), then we derive the rotating shallow water equations under LU, denoted as RSW-LU, following the classical strategy (Vallis, 2017). In particular, we demonstrate one important characteristic of the RSW-LU, namely that it preserves the total energy of the large-scale flow.

2.1 Location uncertainty principles

The LU formulation is based on a temporal-scale-separation assumption of the following stochastic flow:

$$d\mathbf{X}_t = \mathbf{w}(\mathbf{X}_t, t) dt + \boldsymbol{\sigma}(\mathbf{X}_t, t) d\mathbf{B}_t, \quad (2.1)$$

where \mathbf{X} is the Lagrangian displacement defined within the bounded domain $\Omega \subset \mathbb{R}^d$ ($d = 2$ or 3), \mathbf{w} is the large-scale velocity that is both spatially and temporally correlated, and $\boldsymbol{\sigma}d\mathbf{B}_t$ is a highly oscillating unresolved component (also called noise) term that is only correlated in space. The spatial structure of such noise is specified through a deterministic integral operator $\boldsymbol{\sigma} : (L^2(\Omega))^d \rightarrow (L^2(\Omega))^d$, acting on square integrable vector-valued functions $\mathbf{f} \in (L^2(\Omega))^d$, with a bounded kernel $\check{\boldsymbol{\sigma}}$ such that

$$\boldsymbol{\sigma}[\mathbf{f}](\mathbf{x}, t) = \int_{\Omega} \check{\boldsymbol{\sigma}}(\mathbf{x}, \mathbf{y}, t) \mathbf{f}(\mathbf{y}) d\mathbf{y}, \quad \forall \mathbf{f} \in (L^2(\Omega))^d. \quad (2.2)$$

The randomness of such a noise is driven by a functional Brownian motion \mathbf{B}_t (Da Prato & Zabczyk, 2014). The fact that the kernel is bounded, implies that the resulting random flow $\boldsymbol{\sigma}d\mathbf{B}_t$ is a centered (of null ensemble mean) Gaussian process with the well-defined *covariance tensor*:

$$\begin{aligned} \mathbf{Q}(\mathbf{x}, \mathbf{y}, t, s) &= \mathbb{E} \left[(\boldsymbol{\sigma}(\mathbf{x}, t) d\mathbf{B}_t) (\boldsymbol{\sigma}(\mathbf{y}, s) d\mathbf{B}_s)^T \right] \\ &= \delta(t - s) dt \int_{\Omega} \check{\boldsymbol{\sigma}}(\mathbf{x}, \mathbf{z}, t) \check{\boldsymbol{\sigma}}^T(\mathbf{y}, \mathbf{z}, s) d\mathbf{z}, \end{aligned} \quad (2.3)$$

where \mathbb{E} stands for the expectation, δ is the Kronecker symbol and \bullet^T denotes matrix or vector transpose. The strength of the noise is measured by its *variance*, denoted here as \mathbf{a} , and which is given by the diagonal components of the covariance per unit of time:

$$\mathbf{a}(\mathbf{x}, t) dt = \mathbf{Q}(\mathbf{x}, \mathbf{x}, t, t). \quad (2.4)$$

215 We remark that this variance tensor has the same unit as a diffusion tensor ($\text{m}^2 \cdot \text{s}^{-1}$)
 216 and that the density of the turbulent kinetic energy (TKE) can be specified through it
 217 by $\frac{1}{2} \text{tr}(\mathbf{a})/dt$.

218 The previous representation (2.2) is a general way to define the noise, but other
 219 formulations can be conveniently used in practice. In particular, the covariance opera-
 220 tor per unit of time, \mathbf{Q}/dt , admits an orthogonal eigenfunction basis $\{\Phi_n(\bullet, t)\}_{n \in \mathbb{N}}$ weighted
 221 by the eigenvalues $\Lambda_n \geq 0$ such that $\sum_{n \in \mathbb{N}} \Lambda_n < \infty$. Therefore, one may equivalently
 222 define the noise and its variance, based on the following spectral decomposition:

$$223 \quad \boldsymbol{\sigma}(\mathbf{x}, t) d\mathbf{B}_t = \sum_{n \in \mathbb{N}} \Phi_n(\mathbf{x}, t) d\beta_t^n, \quad \mathbf{a}(\mathbf{x}, t) = \sum_{n \in \mathbb{N}} \Phi_n(\mathbf{x}, t) \Phi_n^T(\mathbf{x}, t), \quad (2.5)$$

224 where β^n denotes n independent and identically distributed (i.i.d.) one-dimensional stan-
 225 dard Brownian motions. The specification of those basis functions from data driven em-
 226 pirical covariance matrices enables one to construct specific noises, informed either by
 227 numerical or observational data. This strategy will allow us to devise various forms of
 228 the noise in the following.

229 *Remark 1* Decomposition 2.1 is a temporal decomposition and not a spatial de-
 230 composition as classically formulated through spatial filters and/or decimation opera-
 231 tors in large-eddies simulation (LES) techniques. However, in the case of turbulent flows,
 232 time and spatial scales are related. As a matter of fact, in the inertial range, the turn-
 233 over time ratio for two different scales L and ℓ reads $\tau_L/\tau_\ell \propto (L/\ell)^{2/3}$ and provides a
 234 direct relation between time-scale coarsening and spatial-scale dilation. Unless specif-
 235 ically needed, in the following, we will thus refer to large/small or unresolved scales with-
 236 out differentiating between time or space scales. Note also that temporal filtering has
 237 already been used for the definition of oceanic models (Hecht, Holm, Petersen, & Wingate,
 238 2008) or large-eddies simulation approaches (Meneveau & Katz, 2000).

239 *Remark 2* Decomposition 2.1 is written in terms of an Itô stochastic integral. This
 240 decomposition could have been written in the form of a Stratonovich integral as well.
 241 The calculus associated to this latter integral has the advantage of following the clas-
 242 sical chain rule. However, the Stratonovich noise no longer has zero expectation. This
 243 leads thus to a problematic decomposition with velocity fluctuations of non null ensem-
 244 ble mean. For smooth enough integrands, it is possible to safely move from one form to
 245 the other. For interested readers, more insights on the difference of the two settings and
 246 their implications in stochastic oceanic modelling are provided in (Bauer, Chandramouli,
 247 Chapron, et al., 2020).

248 *Remark 3* The approach could be extended to express flows on arbitrary Riemann-
 249 ian manifolds. In that case it is easier to work directly with the Stratonovich formu-
 250 lation since it is invariant under the change of coordinates. As we consider here only flows
 251 that assume the shallow approximation, the considered representation of the equations
 252 in \mathbb{R}^2 and \mathbb{R}^3 is a very accurate approximation.

253 The core of the LU model representation is based on a stochastic Reynolds trans-
 254 port theorem (SRTT), introduced by (Mémín, 2014), which describes the rate of change
 255 of a random scalar q transported by the stochastic flow (2.1) within a flow volume \mathcal{V} .
 256 In particular, for incompressible unresolved flows, $\nabla \cdot \boldsymbol{\sigma} = 0$, the SRTT can be written
 257 as

$$258 \quad d_t \left(\int_{\mathcal{V}(t)} q(\mathbf{x}, t) d\mathbf{x} \right) = \int_{\mathcal{V}(t)} (\mathbb{D}_t q + q \nabla \cdot (\mathbf{w} - \mathbf{w}_s)) d\mathbf{x}, \quad (2.6a)$$

$$259 \quad \mathbb{D}_t q = d_t q + (\mathbf{w} - \mathbf{w}_s) \cdot \nabla q dt + \boldsymbol{\sigma} d\mathbf{B}_t \cdot \nabla q - \frac{1}{2} \nabla \cdot (\mathbf{a} \nabla q) dt, \quad (2.6b)$$

260

261 where $d_t q(\mathbf{x}, t) = q(\mathbf{x}, t + dt) - q(\mathbf{x}, t)$ stands for the forward time-increment of q at a
 262 fixed point \mathbf{x} , \mathbb{D}_t is introduced as the stochastic transport operator in (Resseguier et al.,
 263 2017c) and $\mathbf{w}_s = \frac{1}{2} \nabla \cdot \mathbf{a}$ is referred to as the Itô-Stokes drift (ISD) in (Bauer, Chan-
 264 dramouli, Chapron, et al., 2020). The transport operator plays the role of the material
 265 derivative in the stochastic setting. The ISD is defined by the variance tensor divergence
 266 and embodies the effect of statistical inhomogeneity of the unresolved flow on the large-
 267 scale component. As shown in (Bauer, Chandramouli, Chapron, et al., 2020), it can be
 268 considered as a generalization of the Stokes drift associated to waves propagation with
 269 the emergence of a similar vortex force and Coriolis correction. In the definition of the
 270 stochastic transport operator in (2.6b), the last two terms describe, respectively, an en-
 271 ergy backscattering from the unresolved scales to the large scales and an inhomogeneous
 272 diffusion of the large scales driven by the variance of the unresolved flow components.
 273 The diffusion term generalizes the Boussinesq eddy viscosity assumption (here with a
 274 matrix eddy viscosity). This term is, nevertheless, directly related to the noise form and
 275 not anymore defined by loose analogy with the molecular dissipation mechanism. The
 276 backscattering term corresponds to an energy source that is exactly compensated by the
 277 diffusion term (Resseguier et al., 2017c).

278 In particular, for an isochoric flow with $\nabla \cdot (\mathbf{w} - \mathbf{w}_s) = 0$, one may immediately
 279 deduce from (2.6a) the following transport equation of an extensive scalar:

$$280 \quad \mathbb{D}_t q = 0, \quad (2.7)$$

281 where the energy of such random scalar q is globally conserved, as shown in (Resseguier
 282 et al., 2017c):

$$283 \quad d_t \left(\int_{\Omega} \frac{1}{2} q^2 d\mathbf{x} \right) = \underbrace{\left(\frac{1}{2} \int_{\Omega} q \nabla \cdot (\mathbf{a} \nabla q) d\mathbf{x} \right)}_{\text{Energy loss by diffusion}} + \underbrace{\left(\frac{1}{2} \int_{\Omega} (\nabla q)^T \mathbf{a} \nabla q d\mathbf{x} \right)}_{\text{Energy intake by noise}} dt = 0. \quad (2.8)$$

284 Indeed, this can be interpreted as a process where the energy brought by the noise is ex-
 285 actly counterbalanced by that dissipated from the diffusion term.

286 **2.2 Derivation of RSW–LU**

287 This section describes in detail the derivation of the RSW–LU system. This model
 288 enriches the formulation described in (Mémin, 2014). Here it is fully stochastic and in-
 289 cludes rotation to suit simulations of geophysical flows on a rotating frame.

290 The above SRTT (2.6a) and Newton’s second principle allow us to derive the fol-
 291 lowing (three-dimensional) stochastic equations of motions in a rotating frame (Bauer,
 292 Chandramouli, Chapron, et al., 2020):

293 *Horizontal momentum equation :*

$$294 \quad \mathbb{D}_t \mathbf{u} + \mathbf{f} \times (\mathbf{u} dt + \boldsymbol{\sigma}_H d\mathbf{B}_t) = -\frac{1}{\rho} \nabla_H (p dt + dp_t^\sigma) + \nu \nabla^2 (\mathbf{u} dt + \boldsymbol{\sigma}_H d\mathbf{B}_t), \quad (2.9a)$$

295 *Vertical momentum equation :*

$$296 \quad \mathbb{D}_t w = -\frac{1}{\rho} \partial_z (p dt + dp_t^\sigma) - g dt + \nu \nabla^2 (w dt + \sigma_z d\mathbf{B}_t), \quad (2.9b)$$

297 *Mass equation :*

$$298 \quad \mathbb{D}_t \rho = 0, \quad (2.9c)$$

299 *Continuity equations :*

$$300 \quad \nabla_H \cdot (\mathbf{u} - \mathbf{u}_s) + \partial_z (w - w_s) = 0, \quad \nabla_H \cdot \boldsymbol{\sigma}_H d\mathbf{B}_t + \partial_z \sigma_z d\mathbf{B}_t = 0, \quad (2.9d)$$

302 where $\mathbf{u} = (u, v)^T$ (resp. $\boldsymbol{\sigma}_H d\mathbf{B}_t$) and w (resp. $\sigma_z d\mathbf{B}_t$) are the horizontal and vertical
 303 components of the three-dimensional large-scale flow \mathbf{w} (resp. the unresolved random

304 flow $\sigma d\mathbf{B}_t$); $\mathbf{f} = (2\tilde{\Omega} \sin \Theta) \mathbf{k}$ is the Coriolis parameter varying in latitude Θ , with the
 305 Earth's angular rotation rate $\tilde{\Omega}$ and the vertical unit vector $\mathbf{k} = [0, 0, 1]^T$; ρ is the fluid
 306 density; $\nabla_H = [\partial_x, \partial_y]^T$ denotes the horizontal gradient; p and $\dot{p}_t^c = dp_t^c/dt$ (infor-
 307 mal definition) are the time-smooth and time-uncorrelated components of the pressure
 308 field, respectively; g is the Earth's gravity value and ν is the kinematic viscosity. In the
 309 following, the molecular friction term is assumed to be negligible and dropped from the
 310 equations. Note that in our setting the continuity equations (2.9d) ensure volume con-
 311 servation (Resseguier et al., 2017c) and mass conservation (2.9c).

312 In order to model the large-scale circulations in the atmosphere and ocean, the hy-
 313 drostatic balance approximation is widely adopted (Vallis, 2017). We now specify the
 314 scaling for this balance in the LU framework. We first adimensionalize the basic vari-
 315 ables as

$$316 \quad (x, y) = \mathcal{L} (x', y'), \quad \mathbf{u} = \mathcal{U} \mathbf{u}', \quad t = \mathcal{T} t', \quad \mathcal{T} = \mathcal{L}/\mathcal{U}, \quad z = \alpha \mathcal{L} z', \quad \alpha = \mathcal{H}/\mathcal{L}, \quad (2.10)$$

317 where the capital letters are used for the characteristic scales of variables and \bullet' denotes
 318 adimensional variables. To scale properly the vertical velocity, we propose to adopt a suf-
 319 ficient incompressible condition (Resseguier et al., 2017c, 2017b) for the resolved com-
 320 ponent in Equation (2.9d), that is

$$321 \quad \nabla_H \cdot \mathbf{u} + \partial_z w = 0, \quad \nabla_H \cdot \mathbf{u}_s + \partial_z w_s = 0. \quad (2.11)$$

322 Note that the latter divergence-free condition on the ISD is usually considered for the
 323 classical Stokes drift (J. McWilliams, Restrepo, & Lane, 2004) although being contro-
 324 versial (Mellor, 2016). The three-dimensional bolus velocity introduced in the eddy-induced-
 325 advection parametrization (Gent & McWilliams, 1990; Gent, Willebrand, McDougall,
 326 & McWilliams, 1995; Griffies, 1998) is also assumed to be incompressible in order to pre-
 327 serve the tracer's moments. In our case, the justification of this constraint is further strengthen
 328 by global energy conservation and a desirable bridge between the classical (global en-
 329 ergy conserving) rotating shallow water system and its stochastic representation. Un-
 330 der the condition (2.11), a classical scaling of the vertical (resolved) velocity holds:

$$331 \quad w = \alpha \mathcal{U} w'. \quad (2.12)$$

332 Apart from these classical scaling numbers, the horizontal component \mathbf{a}_H of the variance/diffusion
 333 tensor \mathbf{a} , which characterizes the strength of the unresolved component, is scaled as

$$334 \quad \mathbf{a}_H = \epsilon \mathcal{U} \mathcal{L} \mathbf{a}'_H, \quad \mathbf{a} = \begin{pmatrix} \mathbf{a}_H & \mathbf{a}_{Hz} \\ \mathbf{a}_{Hz} & a_z \end{pmatrix}, \quad \epsilon = \frac{\mathcal{T}_\sigma}{\mathcal{T}} \frac{\text{EKE}}{\text{MKE}}, \quad (2.13)$$

335 where the specific factor ϵ (Resseguier et al., 2017b) is defined as the ratio between the
 336 eddy kinetic energy (EKE) and the mean kinetic energy (MKE), multiplied by the ra-
 337 tio between the unresolved scale correlation time \mathcal{T}_σ and the large-scale advection time.
 338 From the definitions (2.3) and (2.4), the scaling of the horizontal small-scale flow reduces
 339 to

$$340 \quad \sigma_H d\mathbf{B}_t = \sqrt{\epsilon} \mathcal{L} (\sigma_H d\mathbf{B}_t)'. \quad (2.14)$$

341 In addition, we consider the following scaling between the vertical and horizontal com-
 342 ponents of the unresolved flow:

$$343 \quad \frac{\sigma_z d\mathbf{B}_t}{\|\sigma_H d\mathbf{B}_t\|} \sim \alpha \delta, \quad \text{i.e. } \sigma_z d\mathbf{B}_t = \sqrt{\epsilon} \delta \mathcal{H} (\sigma_z d\mathbf{B}_t)', \quad (2.15)$$

344 where δ is a small factor (Resseguier et al., 2017b). Again, from the definitions (2.3) and
 345 (2.4), the other components of the variance/diffusion tensor scale then as:

$$346 \quad \mathbf{a}_{Hz} = \epsilon \delta \mathcal{U} \mathcal{H} \mathbf{a}'_{Hz}, \quad a_z = \epsilon \delta^2 \alpha \mathcal{U} \mathcal{H} a'_z, \quad \text{i.e. } \frac{a_z}{\|\mathbf{a}_H\|} \sim \alpha^2 \delta^2. \quad (2.16)$$

347 This relation provides a ratio between the vertical and horizontal eddy diffusivities. It
 348 is in practice quite small at large scale (Lévy et al., 2010, 2012).

349 Now, with $\mathbf{f} = 0$ and a constant density ρ_0 , the horizontal momentum equation
 350 (2.9a) implies the following scalings of the rescaled pressures:

$$351 \quad \tilde{p} = p/\rho_0 = \mathcal{U}^2 \tilde{p}', \quad d\tilde{p}_t^\sigma = dp_t^\sigma/\rho_0 = \sqrt{\epsilon} \mathcal{U} \mathcal{L} (d\tilde{p}_t^\sigma)'. \quad (2.17)$$

352 Finally, substituting all the above scalings into Equation (2.9b), the adimensional ver-
 353 tical momentum is given by

$$354 \quad \alpha^2 \left[d_t w' + (\mathbf{u}' \cdot \nabla'_H w' + w' \partial'_z w') dt' + \sqrt{\epsilon} ((\boldsymbol{\sigma}_H d\mathbf{B}_t)') \cdot \nabla'_H w' + \delta (\sigma_z dB_t)' \partial'_z w' \right. \\
 355 \quad - \frac{\epsilon}{2} \left((\nabla'_H \cdot \mathbf{a}'_H + \delta \partial'_z \mathbf{a}'_{Hz}) \cdot \nabla'_H w' + \delta (\nabla'_H \cdot \mathbf{a}'_{Hz} + \delta \partial'_z \mathbf{a}'_z) \partial'_z w' \right. \\
 356 \quad \left. \left. + \nabla'_H \cdot (\mathbf{a}'_H \nabla'_H w' + \delta \mathbf{a}'_{Hz} \partial'_z w') + \delta \partial'_z (\mathbf{a}'_{Hz} \nabla'_H w' + \delta \mathbf{a}'_z \partial'_z w') \right) dt' \right] \\
 357 \quad = -\partial'_z (\tilde{p}' dt' + \sqrt{\epsilon} (d\tilde{p}_t^\sigma)') - dt'/\text{Fr}^2, \quad (2.18)$$

359 where $\text{Fr} = \mathcal{U}/\sqrt{g\mathcal{H}}$ is the *Froude number*. Let us now make the following assumptions:

$$360 \quad \alpha^2 \ll 1, \quad \text{Fr}^2 = \mathcal{O}(1), \quad \epsilon = \mathcal{O}(1), \quad \delta \ll 1. \quad (2.19)$$

361 The acceleration term on the left-hand side (LHS) of Equation (2.9b) has now a lower
 362 order of magnitude than the RHS terms. Restoring the dimensions, the hydrostatic bal-
 363 ance under moderate horizontal uncertainty and weak vertical uncertainty hence boils
 364 down to

$$365 \quad \partial_z (p dt + dp_t^\sigma) = -\rho g dt, \quad \text{i.e. } \partial_z p = -\rho g, \quad \partial_z dp_t^\sigma = 0. \quad (2.20a)$$

366 We remark that the unique decomposition principle of a semimartingale process (Kunita,
 367 1997) is used here to separate the bounded variation component (in terms of dt) and the
 martingale part (in terms of $d\mathbf{B}_t$ or dp_t^σ). Integrating vertically these hydrostatic bal-

Figure 1. Illustration of a single-layered shallow water system (inspired by (Vallis, 2017)). h is the thickness of a water column, η is the height of the free surface and η_b is the height of the bottom topography. As a result, we have $h = \eta - \eta_b$.

368 ances (2.20a) from 0 to z (see Figure 1), we have
 369

$$370 \quad p(x, y, z, t) = p_0(x, y, t) - \rho_0 g z, \quad dp_t^\sigma(x, y, z, t) = dp_t^\sigma(x, y, 0, t), \quad (2.20b)$$

372 where p_0 denotes the pressure at the bottom of the basin ($z = 0$). Following (Vallis,
 373 2017), we assume that the weight of the overlying fluid is negligible, *i.e.* $p(x, y, \eta, t) \approx$

374 0 with η the height of the free surface, leading to $p_0 = \rho_0 g \eta$. This allows us to rewrite
 375 Equation (2.20b) such that for any $z \in [0, \eta]$ we have

$$376 \quad p(x, y, z, t) = \rho_0 g (\eta(x, y, t) - z). \quad (2.20c)$$

377 Subsequently, the pressure gradient force in the horizontal momentum equation (2.9a)
 378 reads

$$379 \quad -\frac{1}{\rho_0} \nabla_H (p dt + dp_t^\sigma) = -g \nabla_H \eta - \frac{1}{\rho_0} \nabla_H dp_t^\sigma, \quad (2.20d)$$

380 which does not depend on z according to Equations (2.20b) and (2.20c). Therefore, the
 381 acceleration terms on the LHS of Equation (2.9a) cannot depend on z , and the shallow
 382 water momentum equation under weak vertical uncertainty ($\delta \ll 1$) can be written fi-
 383 nally as

$$384 \quad \mathbb{D}_t^H \mathbf{u} + \mathbf{f} \times (\mathbf{u} dt + \boldsymbol{\sigma}_H d\mathbf{B}_t) = -g \nabla_H \eta dt - \frac{1}{\rho_0} \nabla_H dp_t^\sigma, \quad (2.21a)$$

$$385 \quad \mathbb{D}_t^H u = d_t u + ((\mathbf{u} - \mathbf{u}_s) dt + \boldsymbol{\sigma}_H d\mathbf{B}_t) \cdot \nabla_H u - \frac{1}{2} \nabla_H \cdot (\mathbf{a}_H \nabla_H u) dt, \quad (2.21b)$$

387 where $\mathbf{u}_s = \frac{1}{2} \nabla_H \cdot \mathbf{a}_H$ is the two-dimensional ISD and \mathbb{D}_t^H denotes the horizontal stochas-
 388 tic transport operator whose expression is recalled in (2.21b) for the u component. The
 389 relation between the unresolved flow component and the random pressure can be fur-
 390 ther specified by considering a scaling of the martingale part of the momentum equa-
 391 tion:

$$392 \quad \sqrt{\epsilon} d_t \tilde{u}' + \sqrt{\epsilon} (\boldsymbol{\sigma}_H d\mathbf{B}_t)' \cdot \nabla_H' u' + \frac{\sqrt{\epsilon}}{R_O} \mathbf{f}' \times (\boldsymbol{\sigma}_H d\mathbf{B}_t)' = \sqrt{\epsilon} \nabla_H' (dp_t^\sigma)', \quad (2.22)$$

393 where $R_O = \mathcal{U}/(f_0 \mathcal{L})$ denotes the Rossby number with $\mathbf{f} = f_0 \mathbf{f}'$, and $\tilde{u} = u - \mathbb{E}(u)$
 394 stands for the martingale part of the horizontal velocity. We note that the scaling $d_t \tilde{u} =$
 395 $\sqrt{\epsilon} \mathcal{U} d_t \tilde{u}'$ is obtained from the variance of the martingale part of the vertical accelera-
 396 tion term (2.18) considering the hydrostatic balance (2.20a) and the continuity equa-
 397 tion (2.11). Therefore, for small Rossby number ($R_O \leq 1$), the random Coriolis term
 398 counter-balances the random gradient pressure force:

$$399 \quad \mathbf{f} \times \boldsymbol{\sigma}_H d\mathbf{B}_t \approx -\frac{1}{\rho_0} \nabla_H dp_t^\sigma. \quad (2.23)$$

400 Besides, under weak vertical uncertainty, the dimensional continuity equations (2.11) and
 401 (2.9d) reduce to

$$402 \quad \nabla_H \cdot \boldsymbol{\sigma}_H d\mathbf{B}_t = \nabla_H \cdot \mathbf{u}_s = 0. \quad (2.24)$$

403 As a result, the vertical integration (from bottom topography η_b to free surface η) of the
 404 continuity equations (2.9d) become

$$405 \quad (w - w_s)|_{z=\eta} - (w - w_s)|_{z=\eta_b} = -h \nabla_H \cdot \mathbf{u}, \quad \sigma d\mathbf{B}_t|_{z=\eta} - \sigma d\mathbf{B}_t|_{z=\eta_b} = 0, \quad (2.25a)$$

407 where $h = \eta - \eta_b$ denotes the thickness of the water column (with a still bottom). On
 408 the other hand, a small vertical (Eulerian) displacement at the top and bottom of the
 409 fluid leads to a variation of the position of a particular fluid element (Vallis, 2017):

$$410 \quad ((w - w_s) dt + \sigma d\mathbf{B}_t)|_{z=\eta} = \mathbb{D}_t^H \eta, \quad ((w - w_s) dt + \sigma d\mathbf{B}_t)|_{z=\eta_b} = \mathbb{D}_t^H \eta_b. \quad (2.25b)$$

412 Combining Equations (2.25), we deduce the following stochastic mass equation:

$$413 \quad \mathbb{D}_t^H h + h \nabla_H \cdot \mathbf{u} dt = 0. \quad (2.26)$$

414 Gathering all the elements derived so-far, we finally obtain the following RSW-LU sys-
 415 tem

416 *(Conservation of momentum)*
 417 $\mathbb{D}_t \mathbf{u} + \mathbf{f} \times \mathbf{u} \, dt = -g \nabla \eta \, dt,$ (2.27a)

418 *(Conservation of mass)*
 419 $\mathbb{D}_t h + h \nabla \cdot \mathbf{u} \, dt = 0,$ (2.27b)

420 *(Random balance)*
 421 $\mathbf{f} \times \boldsymbol{\sigma} d\mathbf{B}_t = -\frac{1}{\rho} \nabla dp_t^\sigma,$ (2.27c)

422 *(Incompressible constraints)*
 423 $\nabla \cdot \boldsymbol{\sigma} d\mathbf{B}_t = 0, \quad \nabla \cdot \mathbf{u}_s = 0,$ (2.27d)

425 where the symbol H for all horizontal variables are dropped for readability reasons. In
 426 Appendix A it is shown that this stochastic system conserves the global energy:

427
$$d_t \int_{\Omega} \frac{\rho}{2} (h|\mathbf{u}|^2 + gh^2) \, d\mathbf{x} = 0. \quad (2.28)$$

428 It shares thus exactly the same energy conservation property as the deterministic one
 429 and beyond their formal resemblance this provides a strong physical link between the
 430 two systems. Moreover, it can be noticed that under a sufficiently weak (horizontal) un-
 431 certainty ($\boldsymbol{\sigma} \approx 0$), the system (2.27) reduces to the classical RSW system, in which the
 432 stochastic transport operator weighted by the unit of time, \mathbb{D}_t/dt , reduces to the ma-
 433 terial derivative.

434 3 Structure-preserving discretization of RSW-LU

435 In order to perform numerical simulations of the RSW-LU (2.27) the noise term
 436 $\boldsymbol{\sigma} d\mathbf{B}_t$ has to be *a priori* parametrized. Its shape is conveniently expressed through a spec-
 437 tral representation and a set of basis functions (2.5). In this work homogeneous as well
 438 as heterogeneous spatial structures have been used and the way they are defined is re-
 439 viewed in Appendix B. The incompressible homogenous noise (see Appendix B1) is de-
 440 fined through a convolution kernel and is associated with Fourier modes orthogonal func-
 441 tions. It is easy to implement through fast Fourier transform (FFT). As shown in Sec-
 442 tion 4.1, this noise was in particular used to assess the numerical energy behavior of the
 443 discrete scheme. However, homogeneous noises, although carefully scaled from a known
 444 energy spectrum established at high resolution, fail to represent inhomogeneity effect en-
 445 coded by spatially varying variance (the variance is constant and diagonal for homoge-
 446 neous incompressible noise). This is detrimental to represent large scale effects shaped
 447 by the small-scale components in geophysical fluid dynamics. As a matter of fact as shown
 448 in (Bauer, Chandramouli, Chapron, et al., 2020), heterogeneous noise shapes the large-
 449 scale flow in a way akin to the action of vortex force associated with the classical Stokes
 450 drift.

451 In this work, two different parameterizations of heterogeneous noise have been used
 452 and are described in Appendix B2. The former consists in calibrating empirical orthog-
 453 onal basis functions (EOF) before the simulation (off-line) from available high-resolution
 454 simulation data while the latter consists in specifying the basis functions from the on-
 455 going (low resolution) simulation (i.e. on-line). The second basis functions do not de-
 456 pend on data and are time evolving whereas the first ones are data driven and station-
 457 ary. A procedure based on dynamic mode decomposition (Schmid, 2010) to define the
 458 noise through evolving basis functions could have been as well used, as proposed by (Gugole
 459 & Franzke, 2019). Such a time evolving basis, learned from a high resolution simulation,
 460 are shown to perform better than stationary EOF based models. We will have the same
 461 type of conclusions for the non-stationary noise experimented here. In Section 4.2, both

462 heterogeneous noises are adopted for identifying the barotropic instability of a mid-latitude
 463 jet.

464 In the following, we focus on an energy conserving (in space) approximation of the
 465 random dynamical system (RSW–LU). In this context, the spatial discretization allows
 466 us to mimic the balance between the global energy brought by the noise and the LU-diffusion
 467 (see Eqn. 2.8) at each time step, hence no additional numerical dissipation or energy in-
 468 crease is introduced into the system. Considering the definition of the stochastic trans-
 469 port operator \mathbb{D}_t in (2.6b), the RSW–LU system in Eqn. (2.27a)–(2.27b) can be explic-
 470 itly written as

$$471 \quad d_t \mathbf{u} = \left(-\mathbf{u} \cdot \nabla \mathbf{u} - \mathbf{f} \times \mathbf{u} - g \nabla \eta \right) dt + \left(\frac{1}{2} \nabla \cdot \nabla \cdot (\mathbf{a} \mathbf{u}) dt - \sigma d\mathbf{B}_t \cdot \nabla \mathbf{u} \right), \quad (3.1a)$$

$$473 \quad d_t h = -\nabla \cdot (\mathbf{u} h) dt + \left(\frac{1}{2} \nabla \cdot \nabla \cdot (\mathbf{a} h) dt - \sigma d\mathbf{B}_t \cdot \nabla h \right). \quad (3.1b)$$

474 We suggest to develop an approximation of the stochastic RSW–LU model (3.1a)–(3.1b)
 475 by first discretizing the deterministic model underlying this system with a structure-preserving
 476 discretization method (that preserves energy in space) and, then, to approximate (with
 477 a potentially different discretization method) the stochastic terms. Here, we use for the
 478 former a variational discretization approach on a triangular C–grid while for the latter
 479 we apply a standard finite difference method. Note that for the methodology introduced
 480 in this manuscript, other spatially energy conserving discretizations rather than the sug-
 481 gested variational integrator could be used too. The *deterministic dynamical core* of our
 482 stochastic system results from simply setting $\sigma \approx 0$ in the equations (3.1a)–(3.1b). To
 483 obtain the full discretized (in space and time) scheme for this stochastic system, we wrap
 484 the discrete stochastic terms around the deterministic core and combine this with an Euler–
 485 Maruyama time scheme.
 486
 487

488 Introducing discretizations of the stochastic terms that do not necessarily share the
 489 same operators as the deterministic scheme has various advantages, as discussed in more
 490 detail in Section 3.2.1. For instance, such a well defined interface between these two model
 491 components minimizes the necessity to adapt the discretization schemes to each other
 492 which, in turn, would permit us to apply our method immediately to existing dynam-
 493 ical cores of global numerical weather prediction (NWP) models.

494 3.1 Discretization of deterministic RSW equations

495 As mentioned above, the deterministic model (or deterministic dynamical core) of
 496 the above stochastic system results from setting $\sigma \approx 0$, which leads via (2.4) to $\mathbf{a} \approx$
 497 0. Hence, Equations (3.1a)–(3.1b) reduce to the deterministic RSW equations

$$498 \quad d_t \mathbf{u} = \left(-(\nabla \times \mathbf{u} + \mathbf{f}) \times \mathbf{u} - \nabla \left(\frac{1}{2} \mathbf{u}^2 \right) - g \nabla \eta \right) dt, \quad d_t h = -\nabla \cdot (\mathbf{u} h) dt, \quad (3.2)$$

499 where we used the vector calculus identity $\mathbf{u} \cdot \nabla \mathbf{u} = (\nabla \times \mathbf{u}) \times \mathbf{u} + \frac{1}{2} \nabla \mathbf{u}^2$. Note that in
 500 the deterministic case d_t/dt agrees (in the limit $dt \rightarrow 0$) with the partial derivative $\partial/\partial t$.
 501

502 3.1.1 Variational discretizations

503 In the following we present an energy conserving (in space) approximation of these
 504 equations using a variational discretization approach. While details about the deriva-
 505 tion can be found in (Bauer & Gay-Balmaz, 2019a; Brecht et al., 2019), here we only give
 506 the final, fully discrete scheme.

507 To do so, we start with introducing the mesh and some notation. The variational
 508 discretization of (3.2) results in a scheme that corresponds to a C-grid staggering of the
 509 variables on a quasi uniform triangular grid with hexagonal/pentagonal dual mesh. Let

Figure 2. Notation and indexing conventions for the 2D simplicial mesh.

510 N denote the number of triangles used to discretize the domain. As shown in Fig. 2, we
 511 use the following notation: T denotes the primal triangle, ζ the dual hexagon/pentagon,
 512 $e_{ij} = T_i \cap T_j$ the primal edge and $\tilde{e}_{ij} = \zeta_+ \cap \zeta_-$ the associated dual edge. Further-
 513 more, we have \mathbf{n}_{ij} and \mathbf{t}_{ij} as the normalized normal and tangential vector relative to edge
 514 e_{ij} at its midpoint. Moreover, D_i is the discrete water depth at the circumcentre of T_i ,
 515 η_{bi} the discrete bottom topography at the circumcentre of T_i , and $V_{ij} = (\mathbf{u} \cdot \mathbf{n})_{ij}$ the
 516 normal velocity at the triangle edge midpoints in the direction from triangle T_i to T_j .
 517 We denote $\bar{D}_{ij} = \frac{1}{2}(D_i + D_j)$ as the water depth averaged to the edge midpoints.

518 The variational discretization method does not require to define explicitly approx-
 519 imations of the differential operators because they directly result from the discrete vari-
 520 ational principle. It turns out that on the given mesh, these operators agree with the fol-
 521 lowing definitions of standard finite difference and finite volume operators:

$$\begin{aligned}
 (\text{Grad}_n F)_{ij} &\triangleq \frac{F_{T_j} - F_{T_i}}{|\tilde{e}_{ij}|}, & (\text{Div } V)_i &\triangleq \frac{1}{|T_i|} \sum_{k \in \{j, i-, i+\}} |e_{ik}| V_{ik}, \\
 (\text{Grad}_t F)_{ij} &\triangleq \frac{F_{\zeta_-} - F_{\zeta_+}}{|e_{ij}|}, & (\text{Curl } V)_\zeta &\triangleq \frac{1}{|\zeta|} \sum_{\tilde{e}_{nm} \in \partial \zeta} |\tilde{e}_{nm}| V_{nm},
 \end{aligned} \tag{3.3}$$

523 for the normal velocity V_{ij} and a scalar function F either sampled as F_{T_i} at the circum-
 524 centre of the triangle T_i or sampled as F_{ζ_\pm} at the centre of the dual cell ζ_\pm . The oper-
 525 ators Grad_n and Grad_t correspond to the gradient in the normal and tangential direc-
 526 tion, respectively, and Div to the divergence of a vector field:

$$(\nabla F)_{ij} \approx (\text{Grad}_n F) \mathbf{n}_{ij} + (\text{Grad}_t F) \mathbf{t}_{ij}, \tag{3.4}$$

$$(\nabla \cdot \mathbf{u})_i \approx (\text{Div } V)_i, \tag{3.5}$$

$$(\nabla \times \mathbf{u})_\zeta \approx (\text{Curl } V)_\zeta. \tag{3.6}$$

531 The last equation defines the discrete vorticity and for later use, we also discretize the
 532 potential vorticity as

$$\frac{\nabla \times \mathbf{u} + f}{h} \approx \frac{(\text{Curl } V)_\zeta + f_\zeta}{D_\zeta}, \quad D_\zeta = \sum_{\tilde{e}_{ij} \in \partial \zeta} \frac{|\zeta \cap T_i|}{|\zeta|} D_i. \tag{3.7}$$

534 3.1.2 Semi-discrete RSW scheme

535 With the above notation, the deterministic semi-discrete RSW equations read:

$$536 \quad d_t V_{ij} = \mathcal{L}_{ij}^V(V, D) \Delta t, \quad \text{for all edges } e_{ij}, \quad (3.8a)$$

$$538 \quad d_t D_i = \mathcal{L}_i^D(V, D) \Delta t, \quad \text{for all cells } T_i, \quad (3.8b)$$

539 where \mathcal{L}_{ij}^V and \mathcal{L}_i^D denote the deterministic spatial operators, and Δt stands for the discrete time step. The RHS of the momentum equation (3.8a) is given by

$$541 \quad \mathcal{L}_{ij}^V(V, D) \triangleq -\text{Adv}(V, D)_{ij} - \mathbf{K}(V)_{ij} - \mathbf{G}(D)_{ij}, \quad (3.9)$$

542 where Adv denotes the discretization of the advection term $(\nabla \times \mathbf{u} + \mathbf{f}) \times \mathbf{u}$ of (3.2),
543 \mathbf{K} the approximation of the gradient of the kinetic energy $\nabla(\frac{1}{2}\mathbf{u}^2)$ and \mathbf{G} of the gradient of the height field $g\nabla\eta$. Explicitly, the advection term is given by

$$545 \quad \begin{aligned} & \text{Adv}(V, D)_{ij} \triangleq \\ & - \frac{1}{\bar{D}_{ij}|\tilde{e}_{ij}|} \left((\text{Curl } V)_{\zeta_-} + f_{\zeta_-} \right) \left(\frac{|\zeta_- \cap T_i|}{2|T_i|} \bar{D}_{ji_-} |e_{ii_-}| V_{ii_-} + \frac{|\zeta_- \cap T_j|}{2|T_j|} \bar{D}_{ij_-} |e_{jj_-}| V_{jj_-} \right) \\ & + \frac{1}{\bar{D}_{ij}|\tilde{e}_{ij}|} \left((\text{Curl } V)_{\zeta_+} + f_{\zeta_+} \right) \left(\frac{|\zeta_+ \cap T_i|}{2|T_i|} \bar{D}_{ji_+} |e_{ii_+}| V_{ii_+} + \frac{|\zeta_+ \cap T_j|}{2|T_j|} \bar{D}_{ij_+} |e_{jj_+}| V_{jj_+} \right), \end{aligned} \quad (3.10)$$

546 where $f_{\zeta_{\pm}}$ is the Coriolis term evaluated at the centre of ζ_{\pm} . Moreover, the two gradient terms read:

$$548 \quad \mathbf{K}(V)_{ij} \triangleq \frac{1}{2} (\text{Grad}_n F)_{ij}, \quad F_{T_i} = \sum_{k \in \{j, i_-, i_+\}} \frac{|\tilde{e}_{ik}| |e_{ik}| (V_{ik})^2}{2|T_k|}, \quad (3.11)$$

$$549 \quad \mathbf{G}(D)_{ij} \triangleq g(\text{Grad}_n (D + \eta_b))_{ij}. \quad (3.12)$$

551 The RHS of the continuity equation (3.8b) is given by

$$552 \quad \mathcal{L}_i^D(V, D) \triangleq -(\text{Div}(\bar{D}V))_i, \quad (3.13)$$

553 which approximates the divergence term $-\nabla \cdot (\mathbf{u}h)$.

554 3.1.3 Time scheme

555 For the time integrator we use a Crank-Nicolson-type scheme where we solve the
556 system of fully discretized non-linear momentum and continuity equations by a fixed-
557 point iterative method. The corresponding algorithm coincides for $\sigma = 0$ with the one
558 given in Section 3.3.

559 3.2 Spatial discretization of RSW-LU

560 The fully stochastic system has additional terms on the RHS of Equations (3.1a)
561 and (3.1b). With these terms the discrete equations read:

$$562 \quad d_t V_{ij} = \mathcal{L}_{ij}^V(V, D) \Delta t + \Delta \mathcal{G}_{ij}^V, \quad (3.14a)$$

$$564 \quad d_t D_i = \mathcal{L}_i^D(V, D) \Delta t + \Delta \mathcal{G}_i^D, \quad (3.14b)$$

565 where the stochastic LU-terms are given by

$$566 \quad \Delta \mathcal{G}_{ij}^V \triangleq \left(\frac{\Delta t}{2} (\nabla \cdot \nabla \cdot (\mathbf{a}u))_{ij} - (\sigma d\mathbf{B}_t \cdot \nabla u)_{ij} \right) \cdot \mathbf{n}_{ij}, \quad (3.14c)$$

$$568 \quad \Delta \mathcal{G}_i^D \triangleq \frac{\Delta t}{2} (\nabla \cdot \nabla \cdot (\mathbf{a}D))_i - (\sigma d\mathbf{B}_t \cdot \nabla D)_i. \quad (3.14d)$$

569 Note that the two terms within the large bracket in (3.14c) comprise two Cartesian com-
 570 ponents of a vector which is then projected onto the triangle edge’s normal direction via
 571 \mathbf{n}_{ij} . The two terms in (3.14d) are scalar valued at the cell circumcenters i .

572 The parametrization of the noise described in Appendix B is formulated in Cartesian
 573 coordinates, because this allows using standard algorithms to calculate EOFs, for
 574 instance. Likewise, we represent the stochastic LU-terms in Cartesian coordinates but
 575 to connect both deterministic and stochastic terms, we will calculate the occurring dif-
 576 ferentials with operators as provided by the deterministic dynamical core (see interface
 577 description below). Therefore, we write the second term in (3.14c) as

$$578 \quad (\boldsymbol{\sigma} d\mathbf{B}_t \cdot \nabla F)_{ij} = \sum_{l=1}^2 (\boldsymbol{\sigma} d\mathbf{B}_t)_{ij}^l (\nabla F)_{ij}^l, \quad (3.15)$$

579 in which $(\boldsymbol{\sigma} d\mathbf{B}_t)_{ij}$ denotes the discrete noise vector with two Cartesian components, con-
 580 structed as described in Appendix B and evaluated at the edge midpoint ij . The scalar
 581 function F is a placeholder for the Cartesian components of the velocity field $\mathbf{u} = (u^1, u^2)$.
 582 Likewise, the first term in (3.14c) can be written component-wise as

$$583 \quad (\nabla \cdot \nabla \cdot (\mathbf{a}F))_{ij} = \sum_{k,l=1}^2 \left(\partial_{x_k} (\partial_{x_l} (a_{kl}F))_{ij} \right)_{ij}, \quad (3.16)$$

584 where a_{kl} denotes the matrix elements of the variance tensor which will be evaluated,
 585 similarly to the discrete noise vector, at the edge midpoints. For a concrete realization
 586 of the differentials on the RHS of both stochastic terms, we will use the gradient oper-
 587 ator (3.4) as introduced next.

588 To calculate the terms in (3.14d) we also use the representations (3.15) and (3.16)
 589 for a scalar function $F = D$ describing the water depth. However, as our proposed pro-
 590 cedure will result in terms at the edge midpoint ij , we have to average them to the cell
 591 centers i .

592 In the following, we will refer to this part of the code that generates the noise on
 593 a Cartesian mesh according to Appendix B as *noise generation module*.

594 **3.2.1 Interface between dynamical core and LU terms**

595 As mentioned above, the construction of the noise is done on a Cartesian mesh while
 596 the discretization of the deterministic dynamical core (variational RSW scheme, Section (3.1)),
 597 corresponding to a triangular C-grid staggering, predicts the values for velocity normal
 598 to the triangle edges and for water depth at the triangle centers. We propose to exchange
 599 information between the noise generation module (see section above) and the dynam-
 600 ical core via the midpoints of the triangle edges where on such C-grid staggered discretiza-
 601 tions the velocity values naturally reside. The technical details about how we realized
 602 such interface in our setup are given in Appendix C.

603 This modular approach with a well defined interface between these two model com-
 604 ponents has various advantages over directly implementing the noise terms on a trian-
 605 gular C-grid mesh as used by the dynamical core. Firstly, this approach allows us to eas-
 606 ily explore various noise types, because using a Cartesian mesh for the latter permits the
 607 usage of standard algorithms for e.g. FFT or singular value decomposition (SVD). In
 608 contrast, exploring these ideas directly on a triangular C-grid would significantly increase
 609 the implementation work. In fact, this manuscript also serves as a proof of concept study
 610 to show that such modular approach indeed works very well.

611 Moreover, the definition of an interface between the two model components should
 612 minimize (or maybe even avoid) the necessity of adapting the numerics of an existing
 613 deterministic core in order to incorporate the discrete stochastic LU-terms. This, in turn,

614 should allow us to apply our method directly to existing dynamical cores of NWP mod-
 615 els.

616 **3.2.2 Computational aspects**

617 In addition to the deterministic scheme we have the terms $\Delta\mathcal{G}^V$ and $\Delta\mathcal{G}^D$ for the
 618 RSW–LU scheme (see Eq. (3.14c) and Eq. (3.14d)). Their discretization can be differ-
 619 entiated into:

- 620 • The noise generation of $\sigma d\mathbf{B}_t$ and \mathbf{a} . The noise generation relies on generating
 621 a fixed number of pseudo-observations and carrying out a SVD to obtain the EOFs.
 622 The SVD can be carried out as an economy-size SVD which depends linearly on
 623 the number of triangles. Currently for LU on-line, EOFs are estimated at each time
 624 step, but less frequent estimations are also possible to save computational costs.
- 625 • The computation of the divergence and gradient in Cartesian coordinates. The
 626 discretization of these operations are described in Appendix C, which results in
 627 matrix vector multiplications.

628 Here, we obtain the discretization of $\Delta\mathcal{G}^V$ and $\Delta\mathcal{G}^D$ using the interface, which is
 629 determined by the underlying discretization of the deterministic scheme. More specif-
 630 ically, we reformulate the differential operators in Cartesian coordinates with the local
 631 derivatives obtained from the deterministic scheme (see e.g. Eq. (C2)). This results only
 632 in a few additional matrix vector multiplications.

633 Optimized standard methods for the noise generation on a Cartesian mesh are po-
 634 tentially more efficient than a direct (and not optimized) implementation on a triangu-
 635 lar mesh. Besides the advantages mentioned above and given that the additional com-
 636 putational costs for interchanging the values via the interface consists of only a few ma-
 637 trix vector multiplications, we advocate our modular approach rather than a direct im-
 638 plementation.

639 **3.3 Temporal discretization of RSW–LU**

640 The iterated Crank-Nicolson method presented in (Brecht et al., 2019) is adopted
 641 for the temporal discretization. Keeping the iterative solver and adding the LU terms
 642 results in an Euler-Maruyama scheme, which decrease the order of convergence of the
 643 deterministic iterative solver (see (Kloeden & Platen, 1992) for details).

644 To enhance readability, we denote V^t as the array over all edges e_{ij} of the veloc-
 645 ity V_{ij} and D^t as the array over all cells T_i of the water depth D_i at time t . The gov-
 646 erning algorithm reads:

Algorithm 1: Time-stepping algorithm

Set iterative solver index $k = 0$ with initial guess at t :

$$\begin{aligned} V_{k=0}^* &= V^t, \\ (D_{k=0}^*) &= D^t + \Delta\mathcal{G}^D(D^t), \end{aligned}$$

and compute $\Delta\mathcal{G}_{ij}^V(V^t)$.

while $\|V_{k+1}^* - V_k^*\| + \|D_{k+1}^* - D_k^*\| > \textit{tolerance}$ **do**

647

$$\begin{aligned} \frac{D_{k+1}^* - D^t}{\Delta t} &= - \frac{\text{Div}(\overline{D_k^*} V_k^*) + \text{Div}(\overline{D^t} V^t)}{2} \\ \frac{V_{k+1}^* - V^t}{\Delta t} &= - \frac{\text{Adv}(V_k^*, D_{k+1}^*) + \text{Adv}(V^t, D^t)}{2} - \frac{\text{K}(V_k^*) + \text{K}(V^t)}{2} - \text{G}(D_{k+1}^*) \\ &\quad + \Delta\mathcal{G}_{ij}^V(V^t) \end{aligned}$$

and set $k + 1 = k$.

end

648

649

650

For all simulations in this manuscript, we used a tolerance of 10^{-6} for simulations on the f-plane and 10^{-10} for simulation on the sphere. In all these cases, our suggested fixed point solver converges in less than 10 iterations.

651

4 Numerical results

652

653

654

655

656

657

658

In this section, we first study the energy behaviour of the numerical RSW–LU scheme introduced above for an inviscid test flow. Then, we show that for a viscous test case, the stochastic model captures more accurately the reference structure of the large-scale flow when compared to the deterministic model under the same coarse resolution. In addition, we demonstrate that the proposed RSW–LU system provides a more reliable ensemble forecast with larger spread, compared to a classical random model based on the perturbations of the initial conditions (PIC).

659

4.1 Inviscid test case – energy analysis

660

661

662

663

664

This first test case consists of two co-rotating vortices on the f -plane. To illustrate the energy conservation of the spatial discretization of the RSW–LU system (2.27), we use the homogeneous stationary noise defined in Section B1 since the two incompressible constraints $\nabla \cdot \sigma d\mathbf{B}_t = 0$ and $\nabla \cdot \nabla \cdot \mathbf{a} = 0$ in (2.27d) are naturally satisfied. Then, no extra steps are required to satisfy the incompressible constraints.

665

Initial conditions

666

667

668

669

670

671

The simulations are performed on a rectangular double periodic domain $\Omega = [0, L_x] \times [0, L_y]$ with $L_x = 5000$ km and $L_y = 4330$ km, which is discretized into $N = 32768$ triangles. We use this resolution for both the deterministic and stochastic simulations. The large-scale flow is assumed to be under a geostrophic regime at the initial state, *i.e.* $f\mathbf{k} \times \mathbf{u} = -g\nabla h$. We use an initial height field elevation (as e.g. in (Bauer & Gay-Balmaz, 2019a)) of the form

672

$$h(x, y, t = 0) = H_0 - H' \left(\exp\left(-\frac{x_1'^2 + y_1'^2}{2}\right) + \exp\left(-\frac{x_2'^2 + y_2'^2}{2}\right) - \frac{4\pi s_x s_y}{L_x L_y} \right), \quad (4.1a)$$

Figure 3. Contour plots of the potential vorticity fields after 2 days for (left) one realization of a LU simulation with homogeneous noise and (right) a deterministic run. The contour interval is $0.4 \text{ days}^{-1} \text{ km}^{-1}$.

673 where the background height H_0 is set to 10 km, the magnitude of the small perturbed
 674 height H' is set to 75 m and the periodic extensions x'_i, y'_i are given by

$$675 \quad x'_i = \frac{L_x}{\pi s_x} \sin\left(\frac{\pi}{L_x}(x - x_{c_i})\right), \quad y'_i = \frac{L_y}{\pi s_y} \sin\left(\frac{\pi}{L_y}(y - y_{c_i})\right), \quad i = 1, 2 \quad (4.1b)$$

676 with the centres of the vertices located at $(x_{c_1}, y_{c_1}) = \frac{2}{5}(L_x, L_y)$, $(x_{c_2}, y_{c_2}) = \frac{3}{5}(L_x, L_y)$
 677 with parameters $(s_x, s_y) = \frac{3}{40}(L_x, L_y)$. To obtain the discrete initial water depth D_i ,
 678 we sample the analytical function h at each cell centre. Subsequently, the discrete geostrophic
 679 velocities at each triangle edge ij at the initial state can be deduced via

$$680 \quad V_{ij} = -\frac{g}{f}(\text{Grad}_t D)_{ij}, \quad (4.2)$$

681 where the Coriolis parameter f is set to 5.3108 days^{-1} . For the LU simulations, the mag-
 682 nitude of the homogeneous noise remains moderate with its constant variance a_0 set to
 683 be $169.1401 \text{ m}^2 \cdot \text{s}^{-1}$.

684 *Analysis of energy conservation*

685 To analyze the energy conservation properties of our stochastic integrator, we use
 686 the above initial conditions to simulate the two co-rotating vortices for 2 days. In Fig-
 687 ure 3, we show contour plots of the potential vorticity (as defined in (3.7)) fields of the
 688 deterministic and stochastic models. We observe that under the moderate noise with a_0
 689 as chosen above, the large-scale structure of the stochastic system is similar to that of
 690 the deterministic run.

691 On the specific staggered grid as shown in Figure 2, the total energy of the shal-
 692 low water equations (A1), for both deterministic and stochastic case, is approximated
 693 by

$$694 \quad E(t) \approx \sum_{i=1}^N \frac{1}{2} D_i(t) |T_i| \sum_{k=j, i_-, i_+} \frac{1}{2|T_i|} h_{ik} f_{ik} (V_{ik}(t))^2 + \frac{1}{2} g (D_i(t))^2 |T_i|. \quad (4.3)$$

695 As shown in (Bauer & Gay-Balmaz, 2019a), the proposed discrete variational integra-
 696 tor (see Section 3.1) together with an iterative Crank-Nicolson time stepping method ex-
 697 hibits a 1st order convergence rate of the energy error with smaller time step size. This
 698 will allows us immediately to simply include the stochastic terms to result in an Euler-
 699 Maruyama type time integrator for stochastic systems (cf. Section 3.2).

In the present work, we consider the energy behavior of the deterministic scheme (i.e. the variational integrator) as reference, which is denoted as $E_{\text{REF}}(t)$ in the following. For the stochastic RSW model, the Euler-Maruyama time scheme might lead to a different behavior with respect to energy conservation when compared to the deterministic model. In order to quantify numerically the energy conservation of the RSW-LU, we propose to measure the relative errors between the mean stochastic energy, denoted as $\bar{E}_{\text{LU}}(t)$, and the reference $E_{\text{REF}}(t)$ by $\bar{E}_{\text{LU}}(t)/E_{\text{REF}}(t)-1$, while using for both the same spatial resolution (see Table 1). This setup allows us to measure the influence of the stochastic terms on the energy conservation relative to the deterministic scheme. Figure 4 shows these relative errors for different time step sizes over a simulation time of 2 days. As we can confirm from the curves, taking successively smaller time steps

$\Delta t \in \{1.7361 \times 10^{-4}, 3.4722 \times 10^{-5}, 1.7361 \times 10^{-5}, 3.4722 \times 10^{-6}, 1.7361 \times 10^{-6}\}$ (in days⁻¹) results in smaller relative errors.

To determine more quantitatively the convergence rate of the stochastic scheme (relative to the reference) with respect to different time step sizes, we defined the following global (in space and time) error measure:

$$\varepsilon(E_{\text{LU}}) = \frac{\|E_{\text{LU}}(t) - E_{\text{REF}}(t)\|_{L^2([0,T])}}{\|E_{\text{REF}}(t)\|_{L^2([0,T])}}, \quad (4.4)$$

where $\|f(t)\|_{L^2([0,T])} = (\int_0^T |f(t)|^2 dt)^{1/2}$ and T is set to 2 days. We determine for an ensemble with 10 members such global errors in order to illustrate the convergence rate of each ensemble member and the spread between those rates. This spread is illustrated as blue shaded area in Figure 5. The area centre is determined by the mean of the errors, and the dispersion of this area is given by one standard derivation (i.e. 68% confident interval of the ensemble of $\varepsilon(E_{\text{LU}})$). Besides, the minimal and maximal values of the errors of the ensemble are represented by the vertical bar-plots. The blue line of Figure 5 shows that the convergence rate (w.r.t. various Δt) of the ensemble mean energy is of 1st order. This is consistent with the weak convergence rate of order $\mathcal{O}(\Delta t)$ of the Euler-Maruyama scheme, cf. Section 3.3.

4.2 Viscous test case - ensemble prediction

Next, we want to show that our stochastic system better captures the structure of a large-scale flow than a comparable deterministic model. To this end, we use a viscous test case and heterogeneous noise.

The viscous test case we use is proposed by (Galewsky, Scott, & Polvani, 2004) and it consists of a barotropically unstable jet at the mid-latitude on the sphere. This strongly non-linear flow will be destabilized by a small perturbation of the initial field, which induces decaying turbulence after a few days. However, the development of the barotropic instability in numerical simulations highly depends on accurately resolving the small-scale flow, which is particularly challenging for coarse-grid simulations. For the same reason, the performance of an ensemble forecast system in this test case is quite sensible to the numerical resolution. In the following, we demonstrate that the RSW-LU simulation on a coarse mesh under heterogeneous noises, provides better prediction of the barotropic instability compared to the deterministic coarse simulation, and produces more reliable ensemble spread than the classical PIC simulation.

Stabilization

The former test case 4.1 consists of smooth enough fields such that no additional sub-grid dissipation is required. In contrast, the following test case consists of the evolution of decaying turbulence, in which sub-grid enstrophy will accumulate quickly, hence an efficient dissipation mechanism is needed, such as the biharmonic eddy viscosity (Galewsky et al., 2004) which is often used in atmospheric and oceanic flow models. Here, we in-

Figure 4. Evolution of the relative L_2 errors between the energy of the mean RSW–LU and the reference, using Δt (blue line), $\Delta t/10$ (red line) and $\Delta t/100$ (yellow line) respectively.

Figure 5. Convergence of the energy path of the RSW–LU to that of the reference w.r.t. time step sizes. The blue line shows the global errors of the ensemble mean energy, the blue area describes the 68% confident interval of the ensemble errors and the dashed line stands for the 1st order convergence rate.

748 clude a biharmonic eddy viscosity with uniform coefficient μ (of unit m^4/s) in the mo-
749 mentum equation:

$$750 \quad d_t V = \left(-\text{Adv}(V, D)_{ij} - \text{K}(V)_{ij} - \text{G}(D)_{ij} - \mu L(V)_{ij} \right) \Delta t, \quad (4.5)$$

751 where:

$$752 \quad L(V)_{ij} = \left(\text{Grad}_n(\text{Div } V)_{ij} - \text{Grad}_t(\text{Curl } V)_{ij} \right)^2. \quad (4.6)$$

754 Although in the evolution equation (3.1a) the dissipative term is energetically ex-
755 actly in balance with the random advection term, the supplementary biharmonic diffu-
756 sion is needed here in this test case to drain the enstrophy pile-up. Using instead a dis-
757 sipative discretization, in which numerical diffusion takes the role of such stabilization,
758 might give stable simulations also without explicit diffusion but then we would lose con-
759 trol of the strength of the diffusion. Note that we used standard biharmonic dissipation,
760 but there exist also energy conserving enstrophy dissipation methods, such as those in-
761 troduced in (McRae & Cotter, 2014) or in (Frank, Gottwald, & Reich, 2003).

762 *Initial conditions*

763 The values of the principle parameters for the simulations are specified in Table
764 1. Under the geostrophic regime, the initial zonal velocity and height is respectively given
765 by

$$766 \quad u(\Theta, t = 0) = \frac{U_0}{e_n} \exp \left(\frac{1}{(\Theta - \Theta_0)(\Theta - \Theta_1)} \right), \quad \text{for } \Theta_0 < \Theta < \Theta_1, \quad (4.7a)$$

$$767 \quad h(\Theta, t = 0) = H_0 - \frac{R}{g} \int_{\Theta} u(\theta, t = 0) \left(2\tilde{\Omega} \sin \theta + \frac{\tan \theta}{R} u(\theta, t = 0) \right) d\theta, \quad (4.7b)$$

769 where $e_n = \exp(-4/(\Theta_1 - \Theta_0)^2)$ is used to rescale the jet magnitude to the maximal
770 value U_0 at the jet's mid-point $\Theta = \pi/4$. As introduced by (Galewsky et al., 2004), in
771 order to initiate the barotropic instability, the following localized bump is included in
772 the height field:

$$773 \quad h'(\Upsilon, \Theta) = H' \cos \Theta \exp \left(- (3\Upsilon)^2 - \left(15 \left(\frac{\pi}{4} - \Theta \right) \right)^2 \right), \quad (4.7c)$$

774 where Υ denotes the longitude. Here, the Coriolis parameter is set to $f = 2 \times 7.292 \times$
775 $10^{-5} \sin(\Theta)$. Analogously to the previous inviscid test case, we then use these analytic
776 functions (4.7) to sample the discrete velocity at the edge mid-points and the height field
777 at the cell centres on the staggered mesh (See Figure 2).

778 For the LU simulations, we use the two heterogeneous noises described in Section
779 B2, based on either the off-line learning of EOFs from the high-resolution simulation data,
780 denoted as LU off-line, or on the on-line estimation of EOFs from the coarse-grid sim-
781 ulation, denoted as *LU on-line*. To allow for comparisons, the strength of these two noises
782 are imposed to be the same. The PIC stochastic model is obtained as follows: first, we
783 perform ensemble simulations of the LU off-line and the LU on-line method over 1 day.
784 Then, each realization of these ensemble runs is used as one initial random state and sim-
785 ulated for the remaining days using the deterministic scheme. We call the PIC simula-
786 tion using the LU off-line method *PIC 1* and the PIC simulation obtained using the LU
787 on-line method *PIC 2*. For each of these stochastic models, an ensemble run with 20 re-
788 alizations is done.

789 Besides a deterministic coarse-grid simulation denoted as *LR*, a deterministic high
790 resolution (HR) simulation is performed that provides us with a reference solution. For
791 all coarse model runs (both deterministic and stochastic), the resolution and paramet-
792 ers given in Table 1 are fixed to be the same. Note that Table 1 states the resolutions
793 and parameters used for these various simulations.

Parameters	Value	Description
(Θ_0, Θ_1)	$(2\pi, 5\pi)/14$ rad	Initial latitude limits
H_0	10.158 km	Background height
H'	120 m	Initial perturbation amplitude
R	6.371×10^3 km	Mean radius of Earth
g	$9.806 \text{ m} \cdot \text{s}^{-2}$	Gravity of Earth
$\tilde{\Omega}$	$7.292 \times 10^{-5} \text{ s}^{-1}$	Angular rotation rate of Earth
U_0	$80 \text{ m} \cdot \text{s}^{-1}$	Maximum zonal velocity
μ_i	$3.975 \times 10^{14} \text{ m}^4 \cdot \text{s}^{-1}$	Fine-grid biharmonic viscosity
μ_L	$3.199 \times 10^{16} \text{ m}^4 \cdot \text{s}^{-1}$	Coarse-grid biharmonic viscosity
Δt_i	12 s	Fine-grid time step
Δt_L	50 s	Coarse-grid time step
N_i	327680	Number of triangles for fine grid (60-km resolution)
N_L	20480	Number of triangles for coarse grid (240-km resolution)

Table 1. Parameter list for simulations of the barotropic instability.

Prediction of barotropic instability

In this section, we compare the predictions of the barotropic instability for different coarse models to that provided by the HR reference simulation. The latter is obtained from the coarse-graining procedure through a bilinear interpolation of the high resolution snapshots.

In Figure 6, we illustrate snapshots of the vorticity fields on the sphere for the reference, LU and deterministic models after a simulation time of 5 days. We can clearly see that the LU ensemble mean better captures the large-scale structure of the reference flow than the deterministic simulation. To better distinguish the differences in the simulations, contour plots of the vorticity fields at day 4, 5 and 6, localized at the mid-latitude of the sphere, are given in Figure 7. From the evolution of the reference vorticity fields we observe that the barotropic instability of the mid-latitude jet starts to develop at day 4. Subsequently, more and more small-scale features emerge and the flow becomes turbulent. Furthermore, both LU on-line and LU off-line simulations exhibit the stretched out wave at day 5 in the same way as the reference does, and that some big vortices start to separate from the wave at day 6. On the other hand, these characteristics are not correctly captured in both PIC 1 and LR simulations. We remark that the results of the PIC 2 simulations are not included in Figure 7, since they behave quite similarly to the PIC 1 runs.

To physically interpret the above results, it is useful to analyze the energy spectra of the different models. From a basic knowledge of the two-dimensional turbulence theory (J. C. McWilliams, 2006), the potential enstrophy is transferred from the large scales to the small scales by the direct cascade, whereas the kinetic energy is transferred from the small scales to the large scales by the inverse cascade. However, introducing only a dissipation mechanism for coarse models often leads to an excessive decrease of the resolved kinetic energy (Arbic, Polzin, Scott, Richman, & Shriver, 2013; Kjellsson & Zanna, 2017).

In our test case, this kind of issue is present in both PIC and the LR simulations, where the small-scale energy and enstrophy are over-dissipated, as illustrated in Figure 8. On the other hand, introducing the non-linear convection by the noise, the LU dynamical systems bring higher turbulent energy and enstrophy to the small scales, which leads to a better structuring of the large-scale flow. For instance, the time evolutions of

Figure 6. Snapshots of the vorticity field on the sphere for different models (with 20480 triangles) after 5 days. From left to right: reference, ensemble mean of LU online and deterministic LR. For the simulations we use the parameters given in Table 1.

826 the ensemble mean of the energy and enstrophy spectra for both LU on-line and LU off-
 827 line simulations are much closer to that of the references. However, the LU off-line spec-
 828 trum changes little over time between wavenumbers 10 and 40 because the a priori ob-
 829 tained EOFs impose at each time step large scale modes on those scales. This is a draw-
 830 back from a stationary noise. Note that these spectra on the sphere are calculated us-
 831 ing the method proposed by (Aechtner, Kevlahan, & Dubos, 2015): first, the energy and
 832 enstrophy is interpolated onto a Gaussian grid, then the spherical harmonics basis are
 833 used to compute the power spectral density.

834 *Evaluation of ensemble forecasts*

835 Once the ensembles have been produced by the random models, we measure the
 836 reliability of the ensemble forecast systems by some simple metrics. But before we do
 837 so, let us first demonstrate qualitatively the time evolution of each ensemble spread and
 838 compare it with the observation trajectory (obtained from the HR reference simulation).
 839 To determine the latter, we evaluate the local vorticity field of the reference at differ-
 840 ent grid points in the region of the mid-latitude jet. These points serve as observation
 841 points. The evolution of the spread of the ensemble forecast systems is then built by the
 842 95% confident interval of its ensemble trajectories at each selected point.

843 In Figure 9 we compare the reference simulation and the simulations obtained from
 844 the off-line noise. To make the figure easier to read, only the off-line noise is shown since
 845 the on-line noise behaves in a similar way. As shown, for the six local points chosen along
 846 the longitude $\Upsilon = -1.53$ rad, the ensemble spreads of the LU off-line system are large
 847 enough to almost always include the observation trajectories, whereas the spreads of the
 848 PIC 1 system are quite small so that the observations are not always contained within
 849 the spread. For the latter, this will result in a wrong coupling of the measurement and
 850 the ensemble system, when performing data assimilation (Gottwald & Harlim, 2013; C. E. Franzke
 851 et al., 2015).

852 To quantify whether the ensemble spread of the forecast system represents the true
 853 uncertainty of the observations (obtained from the reference simulation), the rank his-
 854 togram (Talagrand, Vautard, & Strauss, 1997; Hamill, 2001) is widely adopted as a di-

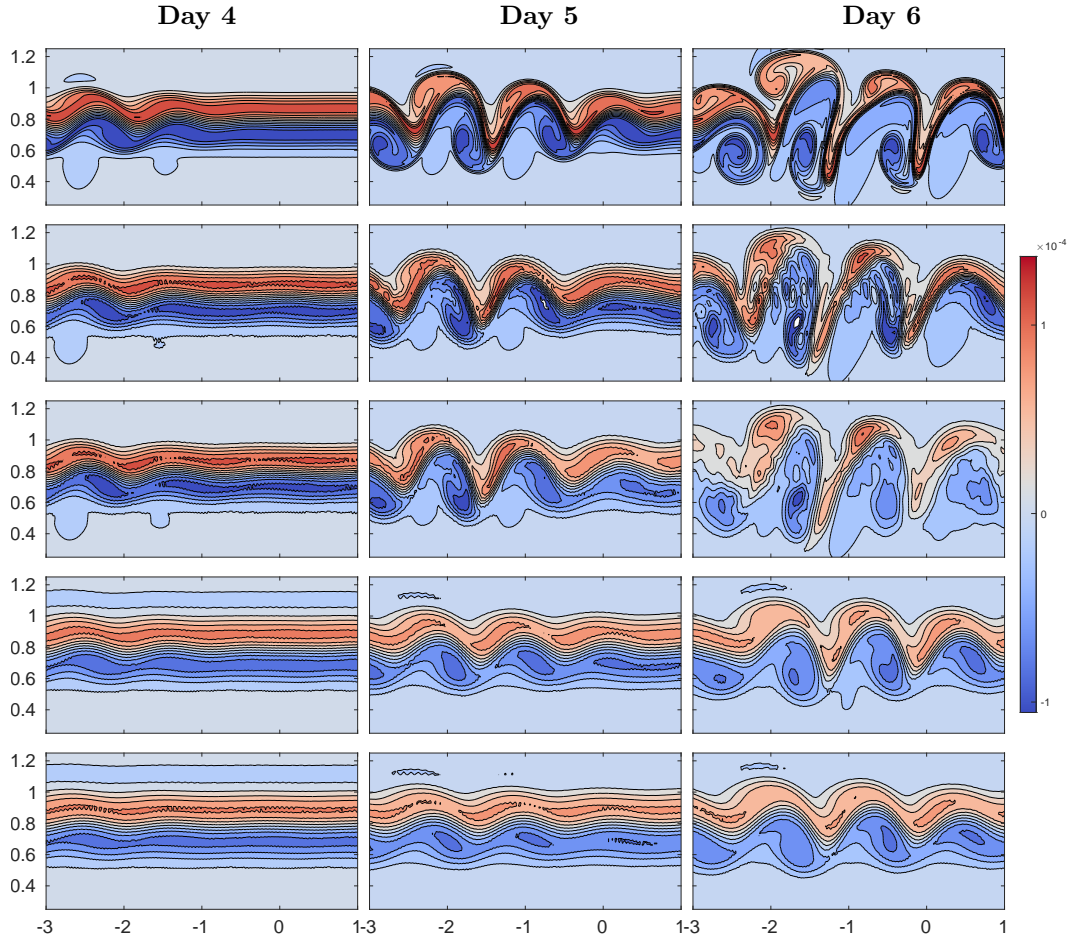

Figure 7. Comparison of the vorticity contour plots along the mid-latitude jet for different models (with 20480 triangles) at day 4, 5 and 6 respectively. From top to bottom: reference, ensemble mean of LU on-line, ensemble mean of LU off-line, ensemble mean of PIC 1 and deterministic LR. The contour interval is fixed to $2 \times 10^{-5} \text{ s}^{-1}$, the x-axis is longitude (in rad) and the y-axis is latitude (in rad). For the simulations we use the parameters given in Table 1.

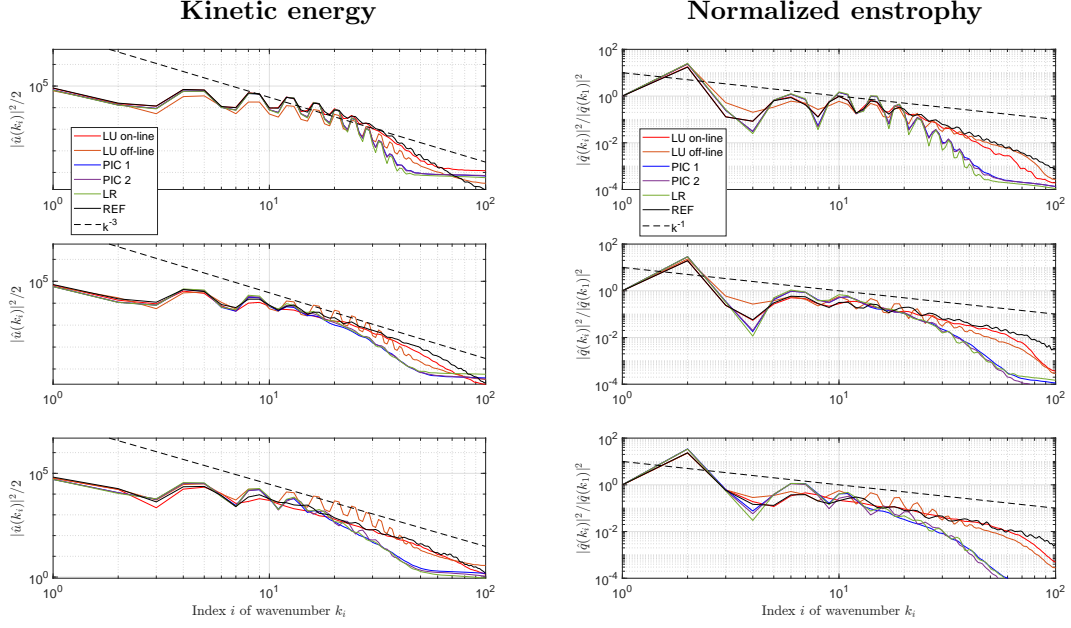

Figure 8. Comparison of the ensemble mean of the kinetic energy (left column) spectrums and the potential enstrophy (right column) spectrums for different models (with 20480 triangles) at day 5 (1st row), 7 (2nd row) and 10 (3rd row) respectively. Note that the potential enstrophy is defined by the square of the potential vorticity and each potential enstrophy spectrum is normalized by its first value at the largest wavenumber. The dashed line is the k^{-3} (left column) and k^{-1} (right column) power law. These power laws for the RSW equations are discussed in (?; Chen et al., 2011).

Figure 9. Comparison of the ensemble spread evolution over 20 days of the vorticity field for the LU-offline (red area) runs and the PIC-offline (blue area) runs, at six different locations $\Theta = (0.4, 0.56, 0.72, 0.88, 1.04, 1.2)$ rad along the longitude $\Upsilon = -1.53$ rad. The observation trajectories are shown by the black lines.

agnostic tool. This approach checks where the verifying observation usually falls w.r.t. the ensemble forecast states which are arranged in an increasing order at each grid point. In an ensemble with perfect spread, each member represents an equally likely scenario, so the observation is equally likely to fall between any two members. To construct the rank histogram in our test case, we proceed as follows:

1. At every grid point \mathbf{x}_i , we rank the N_e vorticity values $\{q^{(j)}(\mathbf{x}_i)\}_{j=1,\dots,N_e}$ of the ensemble from lowest to highest. This results in $N_e + 1$ possible bins which the observations can fall into, including the two extremes;
2. Identify which bin the observation vorticity $q^o(\mathbf{x}_i)$ falls into at each point \mathbf{x}_i ;
3. Tally over all observations $\{q^o(\mathbf{x}_i)\}_{i=1,\dots,N_o}$ to create a histogram of rank.

As shown in Figure 10, the histograms of both random models exhibit a U-shape for a few days in the beginning, while after a simulation time of about 10 days, the histograms of both LU on-line and LU off-line systems become mostly flat. A U-shape indicates that the ensemble spread is too small so that many observations are falling outside of the extremes of the ensemble while a dome-shape indicates the contrary. A flat histogram, in contrast, indicates that the ensemble members and observations are sampled from a common distribution. We observe that the LU off-line system performs slightly better than the LU on-line version. In contrast to these very good ensemble spreads, the histograms of both PIC 2 and PIC 1 systems remain in a U-shape during the entire simulation period which indicates that these systems do not accurately estimate the correct uncertainty around the observations.

It is important to notice that a flat rank histogram does not necessarily imply good forecasts, it only measures whether the observed probability distribution is well represented by the ensemble. To verify that a forecast is reliable, we need more criteria. One necessary criterion (Weigel, 2012) for a reliable ensemble forecast is that the mean squared error (MSE) of the ensemble matches the mean intra-ensemble variance (MEV), up to an ensemble size-dependent scaling factor, *i.e.*

$$\begin{aligned} \text{MSE}(t) &= \frac{1}{N_o} \sum_{i=1}^{N_o} (q^o - \widehat{\mathbb{E}}[q])^2(t, \mathbf{x}_i) \\ &\approx \left(\frac{N_e + 1}{N_e}\right) \frac{1}{N_o} \sum_{i=1}^{N_o} \widehat{\text{Var}}[q](t, \mathbf{x}_i) = \frac{N_e + 1}{N_e} \text{MEV}(t), \end{aligned} \quad (4.8)$$

where $\widehat{\mathbb{E}}[q] = \frac{1}{N_e} \sum_{j=1}^{N_e} q^{(j)}$ and $\widehat{\text{Var}}[q] = \frac{1}{N_e - 1} \sum_{j=1}^{N_e} (q^{(j)} - \widehat{\mathbb{E}}[q])^2$ denote the empirical mean and the empirical variance, respectively.

In Figure 11, we compare the differences in time between the MSE and the MEV, normalized by the squared maximum of the initial vorticity, for the different random models from above. From these curves we can deduce that the LU off-line system exhibits the lowest errors during the entire simulation time of 20 days. In particular, during the first 10 days, these errors are significantly lower when compared to the other models, which can be explained by the fact that the LU off-line system incorporates data from the reference into the ensemble, which increases the reliability of the ensemble forecast. Although the errors between MSE and MEV of the LU on-line system is larger than the LU off-line system from day 5 to day 10, they remain at low level from day 10 onwards, implying that the reliability of the former increases for longer simulation times. In contrast, both PIC 1 and PIC 2 systems show higher error values at most of the times and hence provide less reliable ensembles. We remark that other metrics, such as the continuous ranked probability score (Resseguier et al., 2020; Weigel, 2012), can also be used to measure a calibrated ensemble.

Figure 10. Comparison of the rank histograms for the LU on-line (1st row) runs, the LU off-line (2nd row) runs, the PIC 2 (3rd row) runs and PIC 1 (last row) runs, at day 5, 10, 15 and 20 respectively.

Figure 11. Comparison of the differences between the mean square error (MSE) and the mean ensemble variance (MEV) of the ensemble vorticity fields for the LU on-line (red dashed line) runs, the LU off-line (red solid line) runs, the PIC 2 (blue dashed line) runs and the PIC 1 (blue solid line) runs. Note that these differences are normalized by $q_0 = \|q(\Upsilon, \Theta, t = 0)\|_\infty$.

5 Conclusions

In this study, we introduced a stochastic version of the rotating shallow water equations under location uncertainty (RSW-LU). The derivation is based on a stochastic Reynolds transport theorem, where the fluid flow is decomposed into a large-scale component and a noise term modelling the unresolved small-scale flow. A benefit of this approach is that the total energy is conserved along time for any realization. In order to preserve this structure, we combined an energy (in space) preserving discretization of the underlying deterministic equations of this RSW-LU system with approximations of the stochastic terms that are based on standard finite volume/difference operators.

We could show for an f-plane test case that this approach leads for homogeneous noise to a discretization of the RSW-LU system that preserves (spatially) the total energy. Moreover, using inhomogeneous noise that well captures the impact of small scales on the large-scale flow, we demonstrated that for a barotropically unstable jet on the sphere our proposed RSW-LU model better predicts the development of the instabilities than a comparable deterministic model, while the ensemble spread of the RSW-LU system is more likely to contain the observations compared to an ensemble of deterministic simulations with perturbed initial conditions (PIC). We also showed that the RSW-LU forecast systems follows a common distribution of the observations and is more reliable than the PIC system.

Showing accurate ensemble spreads and reliable forecasting skills, we will next apply our developed RSW-LU system to data assimilation. We will also work towards discretizations of stochastic flow models in the framework of LU that preserve total energy both in space and time to which the present work provides a first step. Exploiting the modular approach of combining different discretizations for deterministic and stochastic terms, in future work we will explore the possibility to consistently extend existing atmospheric and ocean models with stochastic parametrizations. We remark that the stochastic approach proposed in this work could be extended to arbitrary Riemannian manifold. In this setting, it would be easier to first convert the Itô integrals to the Stratonovich representations (see Remark 2), and then transform the latter from Euclidean space to other subspaces of Riemannian manifold under diffeomorphism (Hsu, 2002). This ap-

931 plication could be helpful for the deep atmosphere component of various global numer-
 932 ical weather prediction and climate models, where the domain significantly differs from
 933 Euclidean space.

934 Acknowledgments

935 The authors acknowledge the support of the Mitacs Globalink Research Award and of
 936 the ERC EU project 856408-STUOD. The author Werner Bauer would like to acknowl-
 937 edge funding from NERC NE/R008795/1. Besides, we would like to thank Alexander
 938 Bihlo and Scott MacLachlan for helpful discussions and thank Matthias Achnter for pro-
 939 viding code to compute the energy spectrum on the sphere. We also gratefully acknowl-
 940 edge the reviewers and the associate editor for their insightful comments and suggestions
 941 that helped us to significantly improve this manuscript.

 944 ures can be obtained from <https://zenodo.org/record/5576233>.

945 Appendix A Energy conservation of RSW-LU

946 This appendix demonstrates the energy conservation of the RSW-LU system (2.27).
 947 Let us recall that the density of the kinetic energy (KE) and of the potential energy (PE)
 948 of the large-scale flow in the shallow water system (Vallis, 2017) is, respectively, given
 949 by

$$950 \text{KE} = \int_0^h \frac{\rho_0}{2} |\mathbf{u}|^2 dz = \frac{\rho_0}{2} h |\mathbf{u}|^2, \quad (\text{A1a})$$

$$951 \text{PE} = \int_0^h \rho_0 g z dz = \frac{\rho_0}{2} g h^2, \quad (\text{A1b})$$

953 where $|\mathbf{u}|^2 = \mathbf{u} \cdot \mathbf{u}$ and we assume that $\rho_0 = 1$ and the bottom is flat, *i.e.* $\eta_b = 0$ for
 954 algebraic simplicity. In order to explain the conservation of energy more concisely, we
 955 adopt the following product rule of the stochastic transport operator as derived in (Resseguier
 956 et al., 2017c). For scalar tracers f, g transported by the stochastic flow and incorporat-
 957 ing smooth-in-time external forcings F, G , *i.e.* $\mathbb{D}_t f = F dt$ and $\mathbb{D}_t g = G dt$, we have

$$958 \mathbb{D}_t(fg) = g\mathbb{D}_t f + f\mathbb{D}_t g. \quad (\text{A2})$$

959 Applying this rule to the definition of PE (A1b) and using the mass equation (2.27b),
 960 the PE evolution reads

$$961 \mathbb{D}_t \text{PE} = gh\mathbb{D}_t h = -gh^2 \nabla \cdot \mathbf{u} dt = -2\text{PE} \nabla \cdot \mathbf{u} dt. \quad (\text{A3a})$$

962 Similarly, from both mass equation and momentum equation in (2.27), noting that $\mathbf{u} \cdot$
 963 $(\mathbf{f} \times \mathbf{u}) = 0$ and recalling that $\eta_b = 0$, we derive the evolution of KE (A1a):

$$964 \begin{aligned} \mathbb{D}_t \text{KE} &= h\mathbf{u} \cdot \mathbb{D}_t \mathbf{u} + \frac{1}{2} |\mathbf{u}|^2 \mathbb{D}_t h \\ &= -\frac{1}{2} \mathbf{u} \cdot \nabla (gh^2) dt - \frac{1}{2} h |\mathbf{u}|^2 \nabla \cdot \mathbf{u} dt = -(\mathbf{u} \cdot \nabla \text{PE} + \text{KE} \nabla \cdot \mathbf{u}) dt. \end{aligned} \quad (\text{A3b})$$

967 Subsequently, we deduce the evolution of the total energy density $E = \text{KE} + \text{PE}$,

$$968 \mathbb{D}_t E = -(\nabla \cdot (\mathbf{u} \text{PE}) + E \nabla \cdot \mathbf{u}) dt. \quad (\text{A4a})$$

969 Expanding the stochastic transport operator (2.6b), and including the incompressible
 970 constraints (2.27d), the previous equation can be re-written as

$$971 d_t E = -\nabla \cdot \left((E(\mathbf{u} - \mathbf{u}_s) + \text{PE} \mathbf{u} - \frac{1}{2} \mathbf{a} \nabla E) dt + E \sigma d\mathbf{B}_t \right). \quad (\text{A4b})$$

972 Let us now assume some ideal boundary conditions for the resolved and unresolved com-
 973 ponents:

$$974 \quad \mathbf{u} \cdot \mathbf{n} \Big|_{\partial\Omega} = \mathbf{u}_s \cdot \mathbf{n} \Big|_{\partial\Omega} = \boldsymbol{\sigma} \mathbf{d}\mathbf{B}_t \cdot \mathbf{n} \Big|_{\partial\Omega} = 0, \quad (\text{A5})$$

975 where $\partial\Omega$ denotes the boundary of the fluid domain Ω and \mathbf{n} stands for the outward point-
 976 ing unit normal. Combining Equations (A4b) and (A5), one can show that the total en-
 977 ergy (integration of energy density over domain) is invariant over time:

$$978 \quad d_t \int_{\Omega} \mathbb{E}(\mathbf{x}, t) d\mathbf{x} = - \int_{\partial\Omega} \left((\mathbb{E}(\mathbf{u} - \mathbf{u}_s) + \text{PE} \mathbf{u} - \frac{1}{2} \mathbf{a} \nabla \mathbb{E}) dt + \mathbb{E} \boldsymbol{\sigma} \mathbf{d}\mathbf{B}_t \right) \cdot \mathbf{n} dl = 0, \quad (\text{A6})$$

979 in which the following argument is used

$$980 \quad \mathbf{n} \cdot (\mathbf{a} \nabla \mathbb{E}) dt = \sum_{i,j=1,2} n_i (a_{i,j} dt) \partial_{x_j} \mathbb{E} = \sum_{j=1,2} \mathbb{E} \left[\underbrace{\sum_{i=1,2} n_i (\boldsymbol{\sigma} \mathbf{d}\mathbf{B}_t)^i (\boldsymbol{\sigma} \mathbf{d}\mathbf{B}_t)^j}_{=0 \text{ at } \partial\Omega} \right] \partial_{x_j} \mathbb{E}. \quad (\text{A7})$$

981 Appendix B Parameterizations of noise

982 This section describes briefly some existing parametrization methods for the noise
 983 structure. For interested readers, more technical details can be found in (Resseguier et
 984 al., 2020).

985 B1 Homogeneous noise

986 From Definitions (2.2) and (2.4), a homogeneous noise means that its correlation
 987 operator $\boldsymbol{\sigma}$ is a convolution operator and the variance tensor \mathbf{a} reduces to a constant ma-
 988 trix. To ensure the incompressible constraint (2.27d) of a two-dimensional noise, (Resseguier
 989 et al., 2017b) proposed an isotropic model defined through a random stream function

$$990 \quad \boldsymbol{\sigma}(\mathbf{x}) \mathbf{d}\mathbf{B}_t = \nabla^\perp (\check{\varphi} \star \mathbf{d}\mathbf{B}_t)(\mathbf{x}), \quad (\text{B1})$$

991 where $\nabla^\perp = [-\partial_y, \partial_x]^T$ denotes the perpendicular gradient and $\check{\varphi} \star \mathbf{d}\mathbf{B}_t$ stands for the
 992 random stream function with a convolution kernel $\check{\varphi}$ (and the symbol \star denotes a con-
 993 volution). Both isotropy and incompressibility of the noise result in a (constant) diag-
 994 onal variance tensor $a_0 \mathbf{I}_2$ with the eddy-viscosity-like coefficient a_0 and the two-dimensional
 995 identity matrix \mathbf{I}_2 . For the current work, the divergence-free constraint of the ISD in Equa-
 996 tion (2.27d) is thus naturally satisfied. In practice, the convolution kernel $\check{\varphi}$ is specified
 997 by three parameters: a fixed omni-directional spectrum slope s , a band-pass filter f_{BP}
 998 with support in the range of two wavenumbers κ_m and κ_M , and the coefficient a_0 . In fact,
 999 the Fourier transform of the random stream function $\check{\varphi} \star \mathbf{d}\mathbf{B}_t$ can be defined as:

$$1000 \quad \widehat{\check{\varphi} \star \mathbf{d}\mathbf{B}_t}(\mathbf{k}) \triangleq \frac{A}{\sqrt{\Delta t}} f_{\text{BP}}(\|\mathbf{k}\|) \|\mathbf{k}\|^{-\alpha} \widehat{\xi}_t(\mathbf{k}) \text{ with } \alpha = (3 + s)/2, \quad (\text{B2})$$

1001 where $\widehat{\bullet}$ denotes the Fourier transform coefficient, ξ_t is a space-time white noise, and A
 1002 is a constant to ensure $\mathbb{E} \|\boldsymbol{\sigma} \mathbf{d}\mathbf{B}_t\|^2 = 2a_0 \Delta t$ (see Equations (2.3) and (2.4)) with Δt the
 1003 size of one time stepping and \mathbb{E} the expectation operator. In the simulations, the max-
 1004 imal wavenumber k_M of the noise can usually be chosen as the effective resolution cut-
 1005 off, the minimal wavenumber can be set to $k_m = k_M/2$, and the theoretical spectrum
 1006 slope of a two-dimensional flow is given by $s = -3$. Note that on the sphere homoge-
 1007 neous noise could be generated through spherical harmonics.

1008 B2 Heterogeneous noise

1009 In the following, two parameterizations of the heterogeneous noise are presented.
 1010 These approaches result from the spectral decomposition (2.5) used to construct the EOFs
 1011 of the covariance. However in practice, we work with the Eulerian velocity rather than
 1012 with the Lagrangian displacement.

1013 **B21 Off-line learning of EOFs**

1014 The first method consists in calibrating EOFs from the off-line simulation data with
 1015 the EOFs assumed to be time-independent. To this end, let us consider a set of veloc-
 1016 ity snapshots $\{\mathbf{u}_o(\mathbf{x}, t_i)\}_{i=1, \dots, N_t}$, that have been *a priori* coarse-grained from high-dimensional
 1017 data. Applying the singular value decomposition (SVD) for the fluctuations $\mathbf{u}'_o = \mathbf{u}_o -$
 1018 $\bar{\mathbf{u}}_o$ (where $\bar{\bullet}$ denotes a temporal average) enables us to build a set of EOFs $\{\phi_i\}_{i=1, \dots, N_t}$.
 1019 In addition, we suppose that the fluctuations of the large-scale flow live in a subspace
 1020 spanned by $\{\phi_i\}_{i=1, \dots, m-1}$ (with $m < N_t$) and that the small-scale random drift $\sigma d\mathbf{B}_t/\Delta t$
 1021 lives in the complemented subspace spanned by $\{\phi_i\}_{i=m, \dots, N_t}$ such that

$$1022 \quad \frac{1}{\Delta t} \sigma(\mathbf{x}) d\mathbf{B}_t = \sum_{i=m}^{N_t} \sqrt{\lambda_i} \phi_i(\mathbf{x}) \xi_i, \quad \frac{1}{\Delta t} \mathbf{a}(\mathbf{x}) = \sum_{i=m}^{N_t} \lambda_i \phi_i(\mathbf{x}) \phi_i^T(\mathbf{x}), \quad (\text{B3})$$

1023 where λ_i is the eigenvalue associated to the spatial mode ϕ_i and ξ_i is a standard Gaus-
 1024 sian variable. In practice, there exists an open question in (B3), that is how to adequately
 1025 choose the “splitting mode” ϕ_m . Recently, (Bauer, Chandramouli, Li, & Mémin, 2020)
 1026 proposed to fix it by comparing the time-averaged energy spectrum of the observations
 1027 and the one from a coarse-grid deterministic simulation.

1028 **B22 On-line learning of EOFs**

1029 The previously described data-driven calibration of EOFs is a quite efficient pro-
 1030 cedure. However, such observation data are not always available. (Bauer, Chandramouli,
 1031 Chapron, et al., 2020; Resseguier et al., 2020) proposed an alternative approach in which
 1032 some local fluctuations, called *pseudo-observations* (PSO), are generated directly from
 1033 a coarse-grid simulation. Then, the SVD is applied on those PSO to estimate a set of
 1034 EOFs such that the noise associated with its variance tensor will be built in the same
 1035 way as in (B3). Finally, the magnitude of the noise and variance should be scaled down
 1036 to smaller scales based on a similarity analysis.

1037 The approach proposed first defines N_o PSO (denoted as \mathbf{u}') at each grid point.
 1038 For a given time t and a current coarse velocity \mathbf{u} , we build the PSO by sliding a local
 1039 window of size $N_w \times N_w$ over the spatial grid (with N_w the grid number in one direc-
 1040 tion of the local window). We denote the spatial scale of the window by $L = N_w l$, where
 1041 l is the smallest scale of the simulation. At every grid point $\mathbf{x}_{i,j}$, we list the N_w^2 veloc-
 1042 ity values contained in the window centered at that point:

$$1043 \quad I(\mathbf{x}_{i,j}, t) \triangleq \left\{ \mathbf{u}(\mathbf{x}_{p,q}, t) \left| |p-i| \leq \frac{N_w-1}{2}, |q-j| \leq \frac{N_w-1}{2} \right. \right\}. \quad (\text{B4})$$

1044 Note that appropriate boundary conditions (replication, periodicity, etc.) are adopted
 1045 when looking at a point on the border. Then, independently for each $n \in \{1, \dots, N_o\}$
 1046 and for each point $\mathbf{x}_{i,j}$, we set the value of the PSO $\mathbf{u}'(\mathbf{x}_{i,j}, t, n)$ by randomly choosing
 1047 a value in the set $I(\mathbf{x}_{i,j}, t)$. After this, we average over the realization index n to build
 1048 an empirical covariance. Then, from the SVD we obtain a set of EOFs $\{\phi_i^{(L)}\}_{i=1, \dots, N_o}$,
 1049 and a spectral representation of the small-scale velocity:

$$1050 \quad \frac{1}{\Delta t} \sigma^{(L)}(\mathbf{x}, t) d\mathbf{B}_t = \sum_{i=1}^{N_o} \phi_i^{(L)}(\mathbf{x}, t) \xi_i. \quad (\text{B5a})$$

1051 Since the PSO \mathbf{u}' have been generated at a spatial scale of the window $L = N_w l$, they
 1052 must be scaled down to the “simulation scale” l . In 3D, according to an auto-similarity
 1053 assumption of the velocity fluctuations (Kadri Harouna & Mémin, 2017), the small-scale
 1054 flow $\sigma^{(l)} d\mathbf{B}_t$ associated with its variance tensor $\mathbf{a}^{(l)}$ can be rescaled as

$$1055 \quad \sigma^{(l)} d\mathbf{B}_t = \left(\frac{l}{L} \right)^{1/3} \sigma^{(L)} d\mathbf{B}_t, \quad \mathbf{a}^{(l)} = \left(\frac{l}{L} \right)^{2/3} \mathbf{a}^{(L)}. \quad (\text{B5b})$$

1056 In our case, noting that the small-scale fluctuations are still 3D (even though the ver-
 1057 tical component is not known), we keep the same scaling. As shown in Section 4.2, such
 1058 flow-dependent noise has a good performance in long-term simulation, yet the drawback
 1059 is that the computational costs are significantly higher compared to the previous off-line
 1060 procedure, as the SVD is computed at each time step.

1061 Appendix C Discretization of LU terms

1062 Starting with a given predicted velocity vector with edge values V_{ij} , we first have
 1063 to reconstruct the full velocity vector field from these normal values. We use the recon-
 1064 struction of the vector field in the interior of each triangle proposed by (Perot, Vidovic,
 1065 & Wesseling, 2006):

$$1066 \mathbf{u}_i = \frac{1}{|T_i|} \sum_{k=j, i_-, i_+} |e_{ik}| (\mathbf{x}^{e_{ik}} - \mathbf{x}^{T_i}) V_{ik}, \quad (C1)$$

1067 where $\mathbf{x}^{e_{ik}}$ are the coordinates of the edge midpoint and \mathbf{x}^{T_i} are the coordinates of the
 1068 triangle circumcentre. By averaging values from neighboring triangles, we obtain the cor-
 1069 responding values at the edge midpoints or vertices (see (Bauer, 2013) for details).

1070 This reconstructed velocity vector field will be used to generate the noise as described
 1071 in Appendix B. After the noise has been constructed on the Cartesian mesh, we eval-
 1072 uate the discrete noise vector $(\boldsymbol{\sigma} d\mathbf{B}_t)_{ij}$ and the discrete variance tensor $(\mathbf{a})_{ij}$ at the tri-
 1073 angle edge midpoints. This information will then be used to calculate the LU noise terms
 1074 in (3.14c) and (3.14d).

1075 To calculate the derivatives in these stochastic terms, we use the normal and tan-
 1076 gential gradient operators, i.e. the gradient operator of (3.4). To use it, we have to av-
 1077 erage values, e.g. the term $(a_{kl}F)$, to cell centers and vertices and the resulting differ-
 1078 ential will be an expression located at the edge midpoint. In more detail, we can rep-
 1079 resent the partial derivative in Cartesian coordinates by

$$1080 (\partial_{x_l} F)_{ij} = (\text{Grad}_n F) n_{ij}^l + (\text{Grad}_t F) t_{ij}^l, \quad l = 1, 2. \quad (C2)$$

1081 Concretely, to discretize (3.16), we first compute $(\partial_{x_l} (a_{kl}F))_{ij}$ using Equation (C2). The
 1082 subindex ij indicates that the resulting term is associated to the edge midpoint. To ap-
 1083 ply the second derivative in (3.16), i.e. $(\partial_{x_k} (\partial_{x_l} (a_{kl}F))_{ij})_{ij}$, we proceed analogously,
 1084 i.e. we first average the terms describing the first derivative to cells and vertices and then
 1085 apply once more Equation (C2). We proceed similarly to represent the term ∇F in (3.15).
