RODENT: A FLEXIBLE TOPSIS BASED ROUTING PROTOCOL FOR MULTI-TECHNOLOGIES DEVICES IN WIRELESS SENSOR NETWORKS

Brandon Foubert¹ and Nathalie Mitton¹ ¹Inria, Lille, France,

NOTE: Corresponding author: Brandon Foubert, brandon.foubert@inria.fr

Abstract – Wireless Sensor Networks (WSN) is an efficient tool for many use cases, such as environmental monitoring. However WSN deployment are sometimes limited by the characteristics of the Radio Access Technologies (RAT) they use. To overcome some of these limitations, we propose to leverage the use of Multiple Technologies Network (MTN). What we refer to as MTN is a network composed of nodes able to use several RAT and communicating wirelessly through multi-hop paths. The management of the RAT and routes must be handled by the nodes themselves, in a local and distributed way, with a suited communication protocol stack. Nodes may reach multiple neighbors over multiple RAT. Therefore, each stack's layer has to take the technologies' heterogeneity of the devices into account. In this article, we introduce our custom Routing Over Different Existing Network Technologies protocol (RODENT), designed for MTN. It enables dynamic (re)selection of the best route and RAT based on the data type and requirements that may evolve over time, potentially mixing each technology over a single path. RODENT relies on a multi-criteria route selection performed with a custom lightweight TOPSIS method. To assess RODENT's performances, we implemented a functional prototype on real WSN hardware, Pycom FiPy devices. Unlike related prototypes, ours has the advantage not to rely on specific infrastructure on the operator's side. Results show that RODENT enables energy savings, an increased coverage as well as multiple data requirements support.

Keywords - heterogeneous, Pycom FiPy, routing, TOPSIS, WSN

1. INTRODUCTION

Wireless Sensor Networks (WSN) enable a remote mon-2 itoring of various metrics and many more use cases [1]. 3 Such networks usually rely either on a medium distance 4 Radio Access Technology (RAT) (e.g., IEEE 802.15.4) and 5 a multi-hop path routing or on a long distance RAT (e.g., 6 LoRaWAN) and a star topology. The latter simplifies the network structure and enables a wider coverage. When 8 deployed, WSN usually use a single RAT shared by all 9 nodes. Deployments are thus constrained by the lim-10 its of the chosen RAT, in terms of coverage and perfor-11 mances (throughput, energy consumption, costs, etc). For 12 instance, the network of Sigfox, an operator-based RAT, 13 provides long range communication (up to km) but is not 14 available worldwide. Some RAT are even so constrained 15 that they may not be able to comply with specific data re-16 quirements such as delay-intolerant data, high through-17 put or firmware over-the-air upgrade. Additionally, out-18 door nodes have to bear the weather changes (e.g., rain) 19 which greatly impact the wireless links' quality. 20 Traditional WSN lack flexibility to support multiple use-21

cases. Many different RAT are available for WSN nowa-22 days [2]. Different RAT come with different performances 23 and capabilities. Multiple Technologies Networks (MTN) 24 could overcome the aforementioned issues [3]. With sev-25 eral RAT built-in, the nodes' range of deployment would 26 be extended, as nodes' could switch from one RAT to 27 another at each hop and relay data through multi-hop. 28 MTN's nodes would be able to select the best technology 29

and route available. The choice would be based on the 30 routes availability and costs, in terms of energy, money, 31 etc. If the environment changes, and the selected route's 32 quality decreases, a node can dynamically select a better 33 route and RAT. Nodes that support several data require-34 ments (e.g., temperature and video monitoring) can fol-35 low several paths accordingly. Network resiliency is in-36 creased, as in case of a RAT failure, a node can switch to 37 an alternative technology. 38

Thus, nodes have to use specific methods to au-39 tonomously and dynamically choose which technology 40 is the best suited depending on the data requirements 41 and current context. This issue is known as Network 42 Interface Selection (NIS). Several tools are available in 43 the literature to tackle the NIS problem. Among them 44 are the Multiple Attribute Decision-Making (MADM) 45 methods. MADM methods provide a ranking of different 46 alternatives based on their attributes and their associated 47 weights. One of the most used and studied MADM meth-48 ods is Technique for Order of Preference by Similarity to 49 Ideal Solution (TOPSIS). Said simply, TOPSIS compares 50 candidates based on their mathematical distances to two 51 ideal positive and negative alternatives. 52

However, TOPSIS suffers from an issue known as rank
reversal. A rank reversal happens when the ranking is
modified following the removing of one of the alternatives under study. This can alter the quality of the ranking
and lead to a sub-optimal NIS. In our case, this could outcome in too many useless and costly technology switches.
Moreover, considering hardware constrained WSN nodes,

⁶⁰ TOPSIS computation is resource-intensive. This would ⁶¹ decrease the devices' lifetime and may overload the de-

vices' limited memory which leads to hardware failure.

⁶³ We address those issues in this paper, by proposing a

⁶⁴ lightweight TOPSIS-based NIS method optimized for WSN

65 devices. Furthermore, our method simplifies TOPSIS

66 computations and completely eliminates rank reversal by

67 modifying the TOPSIS normalization algorithm. This re-

sults in less complexity and provides time and energy sav-ings.

Currently available routing protocols are not suited for 70 MTN. In this article, we introduce a novel Routing Over 71 Different Existing Network Technologies protocol (RO-72 DENT) designed for MTN leveraging our custom TOPSIS 73 method. Our contribution takes every RAT of each node 74 into account for the route selection. Every node has a list 75 of available links between itself and its neighbors. Links 76 have associated costs and performances, in terms of de-77 lay, energy consumption etc. A node constructs its routes 78 based on its links' values and the routes' values shared by 79 its neighbors. Criteria for the best route depend on the 80 use case and the requirements data has to meet (e.g., data 81 size, deadline). 82

RODENT is implemented and its performances are as-83 sessed through experimental evaluation. Results show 84 that RODENT increases network flexibility and reliabil-85 ity, decreases energy consumption and enable better con-86 sideration of the data requirements while maintaining a 87 good Packet Delivery Ratio (PDR). Compared to related 88 work, RODENT offers a flexible and dynamic way to over-89 come WSN's limitations without the need of a dedicated 90 infrastructure other than multi-RAT nodes. 91 The contributions of this paper can be summarized as fol-92

93 lows:

We designed a lightweight selection method for WSN based on TOPSIS, free of rank reversal which shows an improvement in the computation time of around 38%, which in turn results in energy savings, while the technology selection is equivalent to using the classic TOPSIS method in 82% of the experiments.

 We designed a multi-technologies routing protocol for WSN based on our custom selection method. It is capable of handling multi-technologies devices and selecting the best route and technologies for specific data requirements.

 We designed and developed a MTN prototype composed of Pycom FiPy devices running a custom implementation of RODENT.

The rest of this paper is organized as follows: Section 2 introduces the literature's works related to MTN and TOPSIS. Section 3 presents the background about MADM and
TOPSIS. Section 4 explains what issues have to be faced
with TOPSIS. Section 5 details our lightweight TOPSIS
method. Section 6 presents our experiments on the selection method and the results we have obtained. Section 7

exposes the network model and assumptions RODENT is based on. Section 8 details RODENT's inner workings. Section 9 presents the hardware used and firmware implemented for our MTN prototype. Section 10 introduces the experimental setup and scenario. Section 11 details the experiments' results. Section 12 concludes this article and lists future works.

Several works have been conducted to mitigate rank reversal in TOPSIS or to apply TOPSIS to NIS. To the best of our knowledge, only few works exist in the literature about multi-technologies network. This section presents related work about TOPSIS and multi-RAT devices.

2.1 TOPSIS method

[4] proposes an iterative TOPSIS method, where TOP-SIS is executed, then the worst alternative is removed from the ranking, and TOPSIS is re-executed, as long as there is more than one alternative in the ranking. The remaining one is selected as communication technology. [5] combines TOPSIS with fuzzy logic, in order to improve how uncertain attributes are taken into account. [6] introduces alternative methods based on TOPSIS, but with different normalization algorithms using maximum and minimum values of the attributes. [7] compares several NIS methods applied to heterogeneous WSN. [8] introduces an original MADM method along with an in-depth analysis of TOPSIS. [9] proposes a new Service-based Interface Selection Scheme algorithm based on TOPSIS to enable NIS applied to vehicle-to-vehicle communications scenarios. [10] details a fast TOPSIS-based NIS technique for vertical handover in heterogeneous emergency communication systems.

Overall, those propositions reduce the probability of occurrence of rank reversal, but does not nullify it because the euclidean normalization is still used. Furthermore, some of the proposed modifications tend to increase the complexity of the TOPSIS method. This would increase the execution time of TOPSIS and in turn the energy consumption of the nodes, thus reducing their lifetime.

To the extent of the authors knowledge, no works has been conducted to propose a rank reversal free TOPSISbased method for NIS specifically for energy constrained devices. Thus, in this in paper we introduce a lightweight TOPSIS-based NIS method that aims not only to reduce the complexity and energy consumption of TOPSIS, but also to completely eliminate rank reversal.

2.2 Multi-technologies networks

The authors of [11] propose an IoT architecture for multi-RAT devices. This architecture is based on a network convergence layer in charge of the multi-RAT management in nodes, and a heterogeneous network controller on the network operator side. It also proposes an hardware platform for the nodes, a polling scheme as well as a compres-

Table 1 – MADM decision matrix.

Fig. $\mathbf{1}$ – Representation of TOPSIS with three alternatives and two attributes.

sion scheme based on Static Context Header Compression
(SCHC). This increases the network flexibility, however it
requires a specific virtual network operator. While the
precedent work focuses on the device side, in [12] the authors propose a cloud-based virtual network operator for
multi-modal LPWA networks. This operator takes care of

multi-modal LPWA networks. This operator takes care of
 configuration and management of heterogeneous LPWAN
 equipment. Again this requires specific infrastructure on
 the operator side.

In [13], a green path selection inter-MAC selection pro-177 tocol is detailed. This protocol allows path selection at 178 the MAC layer while focusing on the energy consumption 179 and radio frequency minimization. However it does not 180 give any information about the routing layer. The arti-181 cle [14] presents the ORCHESTRA framework which man-182 ages real-time inter-technology handovers. It is based on 183 a virtual MAC layer which coordinate the different lay-184 ers from different technology with a unique MAC address. 185 This work also focus on the link layer and not on the rout-186 ing layer. 187

Aforementioned works increase WSN's flexibility. However several limitations are still present, such as the need of a dedicated infrastructure. In this article we propose a routing protocol adapted to MTN, which greatly increase WSN's capabilities while requesting only multi-RAT nodes.

194 3. TECHNOLOGY SELECTION BACKGROUND

¹⁹⁵ Multi-technologies devices have to autonomously select
¹⁹⁶ the best communication technology based on many fac¹⁹⁷ tors. In the literature, several tools are available to per¹⁹⁸ form this Network Interface Selection (NIS): utility and

cost functions, Markov chains, fuzzy logic, game theory,
 data mining, Dempster-Shafer theory, to name a few. Par ticularly, Multi-Attribute Decision Making (MADM) meth ods [15] are commonly used for NIS. MADM methods are
 interesting as they rank several alternatives, based on
 their attributes as well as the relative importance asso ciated to those attributes.

The problem can be modelled with a decision matrix as 206 shown in Table 1. It is composed of $A = \{A_i \mid i =$ 207 1, 2, ..., n the set of the alternatives, $P = \{P_i \mid j =$ 208 1, 2, ..., m the set of the attributes and $W = \{ w_i \mid j = 1 \}$ 209 1, 2, ..., m the set of the weights associated to each at-210 tribute. Applied to NIS, A is the set of technologies, P the 211 set of attributes associated to those and W the data re-212 quirements. The MADM methods take as input a decision 213 214 matrix and output a ranking of the alternatives. Several MADM methods exist, the most known being: Simple Ad-215 ditive Weighting (SAW), Weighting Product (WP), Analyti-216 cal Hierarchy Process (AHP) and Gray Relational Analysis 217 (GRA). 218

One of the most used and studied methods is Technique for Order Preference by Similarity to Ideal Solution (TOP-SIS) [16]. TOPSIS ranks alternatives depending on their relative mathematical distance to the ideal solution. The TOPSIS method runs the following steps:

1. The values x_{ij} of each attribute from the decision matrix (cf. Table 1) are normalized according to Equation (1).

$$r_{ij} = \frac{x_{ij}}{\sqrt{\sum_{i=1}^{n} x_{ij}^2}}$$
(1)

2. The normalized values r_{ij} are weighted according to Equation (2).

$$w_{ij} = w_j r_{ij}, \ \sum_{j=1}^m w_j = 1$$
 (2)

3. The positive and negative ideal alternatives *A*⁺ and *A*⁻ are constructed according to Equation (3).

$$A^{+} = [v_{1}^{+} ... v_{m}^{+}] A^{-} = [v_{1}^{-} ... v_{m}^{-}]$$
(3)

4. The attribute values of the ideal alternatives are determined according to Equation (4) for upward attributes (*e.q.* range) or Equation (5) for downward attributes (*e.q.* latency).

$$v_{j}^{+} = Argmax\{v_{ij}, i = 1, ..., n\}$$

$$v_{j}^{-} = Argmin\{v_{ij}, i = 1, ..., n\}$$
(4)

$$v_{j}^{+} = Argmin\{v_{ij}, i = 1, ..., n\}$$

$$v_{i}^{-} = Argmax\{v_{ij}, i = 1, ..., n\}$$
(5)

219

220

221

222

	P_1	P_2	P_3
A_1	1.024537	7.828443	8.650221
A_2	4.226149	0.09865402	4.673396
A_3	8.026353	5.455392	2.536936
A_4	1.700537	1.398855	0.7656412

5. The distances between each alternative and the positive and negative ideal alternatives A^+ and A^- are computed according to Equation (6).

$$S_{i}^{+} = \sqrt{\sum_{j=1}^{m} (v_{j}^{+} - v_{ij})^{2}}$$

$$S_{i}^{-} = \sqrt{\sum_{j=1}^{m} (v_{j}^{-} - v_{ij})^{2}}$$
(6)

6. Finally, the relative closeness to the ideal solution is computed for each alternative according to Equation (7) and a ranking is established based on those values.

$$C_{TOPSIS} = \frac{S_i^-}{S_i^- + S_i^+}$$
(7)

When using TOPSIS for NIS, the technology with the highest value of C_{TOPSIS} is selected. A graphical representation of the TOPSIS method with three alternatives and two attributes is depicted in Figure 1.

4. TOPSIS PROBLEM STATEMENT

TOPSIS is particularly interesting, as it grades alternatives 229 based not only on the closeness from the best alternative 230 but also on the distance from the worst one. However, 231 TOPSIS suffers from an issue known as rank reversal that 232 can happen when a non-optimal alternative is removed 233 from the ranking. This can alter the quality and perti-234 nence of the ranking. Rank reversal is an issue common to 235 several MADM methods. With an ideal method, the rank-236 ing of alternatives should not be altered when another al-237 ternative is removed. The cause of rank reversal is the 238 normalization algorithm. Indeed, the TOPSIS normaliza-239 tion (a.k.a. euclidean normalization) computes the nor-240 malized values for an attribute based on the values of all 241 the other alternatives for that same attribute. Thus if set 242 A changes, the result of Equation (1) also changes, which 243 may modify the final ranking. 244

To clarify rank reversal let us consider an example. Ta-245 ble 2 represents a simple decision matrix randomly filled. 246 Running TOPSIS on it outputs a ranking order corre-247 sponding to $[A_1, A_3, A_2, A_4]$. If the alternative A_4 was to 248 be removed from the ranking (e.g. because of a broken 249 link for example), it is expected that the ranking of the 250 remaining alternatives should not be altered and there-251 fore should correspond to $[A_1, A_3, A_2]$. However, running 252 TOPSIS on Table 2 after removal of alternative ${\cal A}_4$ out-253 puts a ranking corresponding to $[A_3, A_1, A_2]$. This corre-254 sponds to a rank reversal. Applied to NIS, it means that the 255

²⁵⁶ loss of the wireless link of technology A_4 would change the selected technology from A_1 to A_3 . This would cause a technology switch which will require energy and does not bring any overall improvement.

It is to be noted that rank reversal is not a theoretical 260 issue for multi-technologies WSN devices. Actually, the 261 wireless technologies' links' quality depends on many fac-262 tors such as atmospheric and environmental conditions, 263 which vary heavily across the year. This may results in 264 broken links, thus removing a technology from the set 265 of alternatives and potentially resulting in rank reversal, 266 as seen in the previous example. The frequency of such 267 events is entirely dependent on external factors and can-268 not be anticipated, thus links' quality has to be considered 269 270 in the NIS process. Rank reversal could lead to the selection of a sub-optimal technology, on top of spending en-271 ergy for switching between technologies. 272

A second issue posed by TOPSIS-based NIS on constrained devices is the complex computations that are required. TOPSIS method as seen in Section 3 is based on computations that use numerous operations and memory accesses. WSN devices are generally hardware constrained, energy-limited and a repetitive execution of the TOPSIS method will have a considerable impact on the energy consumption of nodes. As an example, the Pycom FiPy's CPU [17] holds two cores that can go up to 240 MHz. A classic laptop CPU, *e.g.*, the Intel® Core™ i7-8650U, holds four cores that can go up to 4.20 GHz.

5. LIGHTWEIGHT TOPSIS FOR WSN

As stated in Section 4, the rank reversal issue is due to TOPSIS' normalization which computes normalized values based on all the other alternatives' values. Moreover, this normalization method is rather complex, and may increase the energy consumption of nodes.

Thus, we propose to use a simplified normalization method, which will not cause rank reversal and simplify the computations. Rank reversal happens because other alternatives are taken into account when computing normalized values. Thus, our proposition is to compute those values without taking into account other alternatives values. Therefore, we need a stable normalization referential to measure our values against. We know that multitechnologies devices have a fixed set of technologies available. Those are not supposed to change after deployment, and they have fixed maximum and minimum capabilities. We propose to use those maximum and minimum bounds as referential for our normalization.

5.1 Algorithm

That simplification takes the form of Algorithm 1, which replace Equation (1) in the steps of our lightweight TOP-SIS. Each value x_{ij} is normalized by being divided with the upper or the lower bound of its attribute *j*. Upward attributes values are divided by their upper bound, while downward attributes divide their lower bound. The set

Algorithm 1 Lightweight normalization

Require: x_{ij} the raw value of each attribute j for each candidate *i* for each attribute P_i do if P_i is an upward attribute **then** $\vec{B_j^+}$ is the upper bound of P_j $r_{ij} = \frac{x_{ij}}{B_i^+}$ else if P_j is a downward attribute then B_j^- is the lower bound of P_j $r_{ij} = \frac{B_j^-}{x_{ii}}$ end if end for **return** r_{ij} the normalized value of x_{ij}

 $B = \{B_{j}^{+}, B_{j}^{-} \mid j = 1, 2, ..., m\}$ is composed of the up-310 per and lower bounds of each attribute j, such that $\forall x \in$ 311 $B, 0 < x < +\infty$. B is stable, thus normalized values from 312 the alternatives will not be altered by the removing of any 313 other alternative. This completely eliminates rank rever-314 sal and reduces algorithmic complexity at once. Indeed, 315 Equation (1) requires the computation of the denomina-316 tor $\sqrt{\sum_{i=1}^{n} x_{ij}^2}$ for each value of *j* (for *m* attributes). This 317 is not required with our bounded normalization and only 318 the division between the bound and the value is com-319 puted. Knowing the fixed bounds allows us to simplify 320 TOPSIS further: Equation (3) is used to establish the ideal 321 positive and negative alternatives. Extreme values are 322 found according to Equation (4) for upward attributes or 323 Equation (5) for downward ones. Those operations re-324 quire many comparisons. With bounded normalization, 325 we can simplify the determination of the ideal alterna-326 tives: determination of A^+ and A^- is trivial, as the nor-327 malized maximum and minimum bounds of the attributes 328 are respectively equals to 1 and 0. Thus, Equations (4) 329 and (5) can be simplified by Equation (9). In turn, deter-330 mination of the ideal alternatives according Equation (3) 331 shows that these are static and shown in Equation (8). 332 Finally, distances computation according to Equation (6) 333 can be simplified by Equation (10). Indeed, as the ideal al-334 ternatives are known and static, we thus know that $v_i^+ =$ 335 1 and $v_i^- = 0$. 336

Those simplifications reduce the complexity of the TOP-337 SIS method. Moreover, as the normalization uses a stable 338 referential, rank reversal probability is eliminated. Those 339 modifications thus reduce the time required for execu-340 tion, as we will see in Section 10. 341

356

357

The reduced complexity of our algorithm can be assessed 343 with an algorithmic complexity comparison. As big Onotation is only pertinent for large inputs, we choose to quantify the number of operations spared with our 346 method instead of classic TOPSIS. We consider one operation as one of the four basic arithmetic operations: addition, subtraction, multiplication and division. We also consider square root and value comparison as a single operation. This is just an estimation and is not exact as a square root is decomposed into multiple simpler operations when computed. However, as the exact decomposition is dependent on the hardware, it is irrelevant to assign a precise operation cost to a square root. Hereafter we consider n and m to be the dimensions of the decision matrix.

Firstly, Equation (1) requires at least 3nm operations, 358 while using Algorithm 1 instead reduces it to nm oper-359 ations. Replacing Equations (3), (4) and (5) by Equa-360 tions (8) and (9) spares the cost of the min-max algorithm, 361 thus 2(mn-1) operations. Finally, using Equation (10) 362 instead of Equation (6) spares nm operations. Our propo-363 sition thus spares a total of 5mn - 2 operations. 364

SELECTION EXPERIMENTS & RESULTS 6. 365

We implemented both algorithms in MicroPython on FiPy 366 modules from Pycom, coupled with Pytrack expansion 367

Table 3 - Attributes' weights.

Fig. 4 - Rank reversal prevalence as a function of the decision matrix' size.

boards. Both are depicted in Figures 2 and 3. Those 368 devices offer five different wireless communication tech-369 nologies, and provide hardware close to the one used 370 in WSN. The available technologies on FiPy platform are 371 WiFi, LoRa, Sigfox, LTE-M, NB-IoT and Bluetooth Low En-372 ergy. Each one comes with different performances, based 373 on different metrics such as: energy consumption, eco-374 nomical cost, throughput, delay, loss rate, etc. Attributes 375 of each technology are used to fill the decision matrix val-376 ues x_{ij} used as input for the NIS algorithms. Weights as-377 sociated to attributes are determined based on the data 378 requirements. Table 3 shows an example set of weights 379 that could be used: for regular monitoring data the weight 380 and thus importance of the energy consumption will be 381 higher. This would probably lead to an NIS of the best 382 energy-efficient technology (e.g., Sigfox). On the contrary, 383 for an alarm the weight of delay will be higher, leading to 384 an NIS of the fastest technology (e.g., WiFi). 385

Rank reversal prevalence 6.1 386

We wanted to know how painful can be a rank reversal 387 using TOPSIS for NIS. We ran experiments to quantify the 388 prevalence of rank reversal using TOPSIS. The nodes ex-389 ecute the following steps: i) create a random matrix, ii) 390 run TOPSIS on it and *iii*) compute the resulting ranking. 391 Then we randomly remove one of the potential alterna-392 tive and the new ranking was computed. TOPSIS was run 393 again on the matrix without the alternative removed from 394 the ranking, and the resulting ranking was compared with 395 the previous ranking. If the order of remaining options 396 was different, then a rank reversal happened. 397

Results are highly dependent on the size of the matri-398 ces. Generally, the bigger the decision matrix, the more 399 rank reversals as we can see in Figure 4. Large matri-400

Fig. 5 - Classic and lightweight TOPSIS run times.

ces are not a current realistic representation of NIS in WSN. Multi-technologies WSN nodes have several technologies available, but it is very unlikely that plain nodes carry hundreds of technologies. Similarly, technologies can have tens of attributes compared, but it is unlikely to be hundreds. Nonetheless, later, hardware will integrate more and more computing resources and communication technologies so our proposition will be able to scale with them. Still, we can see that even with small (5×5) matrices as we can obtain with FiPv modules, rank reversal happens approximately in 30% of the experiments. Rank reversal may cause useless technology switches, that are costly energy-wise. Larger matrices imply more frequent rank reversal, which emphasizes the need for a solution as ours. This is considerable if we assume TOPSIS to be run periodically to select the best technology after attributes 417 or data requirements change.

6.2 **Computation time**

We compare the performances of a classic TOPSIS with our lightweight TOPSIS. We measure the time needed for the algorithms completion with the Timer library available for the FiPy as well as the similarity between the resulting NIS. It is worth noting that TOPSIS does not embed an objective comparison referential to estimate the quality of a ranking. However, TOPSIS is considered to produce a good quality ranking and is thus commonly used as a point of comparison. The obtained results are visible in Figure 5.

We obtain a mean speed up of the computing time of 38%. At the same time, we still maintain a similarity with TOP-SIS ranking in 82% of the experiments. Note that the ranking in the remaining 18% of the experiments cannot be qualified as worse for all cases since it mainly depends on the application and of what is expected or required. The ranking is only different from TOPSIS' ranking, which we used as a reference, but is not a ground truth. If we look at what we obtained when using a (5×5) matrix for a population of 7000 experiments with the results rounded to two decimal places, the mean execution time of the

Node E (LoRa)	37	0	72

classic TOPSIS is 4.79 ms, while the mean execution time 440 of our lightweight TOPSIS is 2.96 ms. This means that a 441 node could benefit from a mean time of 1.83 ms longer 442 sleep periods between two TOPSIS executions. Based on 443 the FiPy CPU data-sheet [17], with a maximum CPU con-444 sumption of 68 mA and a power supply of 3.6 V, it would 445 save up to approximately 448 µJ per TOPSIS run. Data-446 sheets are notoriously optimistic, so in practice the en-447 ergy savings could be even more significant. The standard 448 deviation is of 0.05 ms, and the confidence intervals are 449 $+/-2.76 * 10^{-3}$ ms and $+/-2.48 * 10^{-3}$ respectively 450 for classic TOPSIS and for our lightweight TOPSIS, with a 451 confidence level of 99.999%. Larger matrices offer similar 452 results. 453

454 7. NETWORK MODEL & ASSUMPTIONS

We based the design of RODENT on a specific network
model and assumptions made on the lower layers of the
communication stack. In this section we describe those
model and assumptions.

459 7.1 Network model

In WSN, the nodes usually follow one or multiple traffic 460 patterns [19]. In this work, we assume that the nodes 461 communicate in a convergecast pattern. Nodes forward 462 packets exclusively to sink nodes. The nodes taking part 463 in an MTN are heterogeneous in terms of RAT. We assume 464 that the network is a connected graph where we consider 465 every link from every node independently of their RAT *i.e.*, 466 there can be several links between a single pair of nodes. 467 Nodes can meet several data requirements (e.g., monitor-468 ing, alarm, etc.), as long as those requirements are known 469 by every node in the MTN. An MTN is depicted in Figure 6. 470 In this example, node B (N_B) measures temperature and 471 is not in range of a Sigfox or NB-IoT base station. However 472

Table 5 – Example route matrix RM_D .

	Energy	Money	Bit-rate	Hops
Sigfox BS	12	102	22	1
NB-IoT BS	151	87	174	1
Node E (LoRa)	49	102	94	2

Table 6 - Requirements vectors.

	Energy	Money	Bit-rate
<i>RV_{monitoring}</i>	0.6	0.3	0.1
RV _{alarm}	0.1	0.1	0.8

 N_B can forward its data to N_A or N_C using LoRa. These latter can then offload N_B 's data to a base station with a different RAT.

500

RODENT aims to support multiple use cases. Nodes can have multiple purposes (*e.g.*, monitoring temperature, video recording). The data requirements differ depending on the use case. For instance, for video data, we need a RAT with a high bit-rate to ensure low delay and jitter. For an alarm, we need a very short delay but not necessary high bandwidth. For regular and small monitoring data, the focus is on saving the nodes' energy. A single node can have multiple data requirements *e.g.*, sending regular monitoring data of a rainfall and an alarm in case of a flood. Thus the route selection must satisfy as best as possible all nodes' data requirements.

7.3 Assumptions on communication stack

This article focuses on the network layer, specifically routing. We assume that the other communication stack's layers are comprised of protocols suited to MTN and that the physical and link layers are able to assess the availability and quality of links toward the nodes' neighbors *i.e.*, nodes or base stations. We assume that this process is possible for every RAT. We consider that those layers are able to gather or estimate information about the cost and performances of each link *i.e.*, energy cost, bit-rate, etc. Radio link quality estimation in WSN is a well studied subject [20].

RODENT takes a link matrix as input, to which we refer 501 to as LM_x for node x. LM_x 's size depends on multiple fac-502 tors: the number of characteristics, the number of RAT 503 available, and the number of x's neighbors. For example, 504 N_D in Figure 6 could have a link matrix LM_D such as the 505 one in Table 4. LM_D is comprised of every available link 506 between N_D and its neighbors, and the characteristics of 507 those links. 508

⁵⁰⁹ We refer to the route matrix of node x as RM_x . For route ⁵¹⁰ selection, RM_x is composed of all the routes available for ⁵¹¹ node x. RM_x 's attributes are relative to the routes *e.g.*, the ⁵¹² number of hops, expected transmission count or the total ⁵¹³ energy consumption. For example, N_D in Figure 6 could ⁵¹⁴ have a route matrix RM_D such as the one in Table 5. TOP-⁵¹⁵ SIS takes as input a set of weights for each attribute. The

Fig. 7 - RODENT packet structure.

weights represent the importance of each attribute in the ranking process. We refer to a set of weights as a Requirements Vector (*RV*). *RV_x* is the requirements vector for use case *x* e.g., *RV_{monitoring}*. For route selection *RV*'s values are set based on the data requirements that the node have to meet e.g., prioritize speed over energy consumption, and such that *RV* { $e_n \in RV \mid \sum_{n=1}^{|RV|} e_n = 1$ }. Examples requirements vectors are depicted in Table 6.

524 8. ROUTING OPERATIONS

The distinctive feature of RODENT is to enable multi-RAT 525 routes. Each route offers different cost and performances. 526 In this section we detail RODENT's routing operations. 527 The following notations are used further. Node i is re-528 ferred to as N_i . Nodes that are in the vicinity of N_i are 529 called neighbors. The set of N_i 's neighbors is referred to 530 as NBR(i) and $NBR(i)_i$ is the node j such that $N_i \in NBR(i)$. 531 A neighbor N_i of N_i has at least one link with N_i . For RAT 532 x, such a link is referred to as L_{ij}^x . Consequently, the route 533 from N_i that follows link L_{ij}^x is referred to as R_{ij}^x . 534

535 8.1 Overview

Let's consider the operations of N_D and N_E from Figure 6 536 as an example. N_D boots without any knowledge of its 537 surroundings. N_D 's link layer scans the environment for 538 every RAT and builds its link matrix LM_D as in Table 4. 539 Based on LM_D , the network layer starts to build the route 540 matrix RM_D . The direct links between N_D and the base 541 stations are registered in RM_{D} as single-hop routes. N_{E} 542 meanwhile does the same, and selects its only available 543 route toward the Sigfox base-station. ${\it N}_{E}$ advertises its 544 route which is received by ${\cal N}_D$ through their LoRa link 545 L_{ED}^{LoRa} . N_D constructs its third route by adding the route's 546 and link's costs. RM_D is then similar to Table 5. N_D then 547 selects a best route for each of its RV. The selection is 548 made independently of the RAT and based only on the 549 routes' costs and performances. In this case and consider-550

ing Table 6, the best route for $RV_{monitoring}$ is the one toward the Sigfox base station because low energy consumption is favored. The best route for RV_{alarm} is the one toward the NB-IoT base station because high bit-rate is favored. N_D then starts to advertise and use its best routes.

6 8.2 Packet structure

RODENT packets' structure is depicted in Figure 7. A packet is composed of three parts: (i) the header (ii) the payload (iii) the trailer. The header contains the required control data for RODENT. The Network Identifier is a two byte value shared by all nodes and is used to differentiate RODENT's communication. The Source Identifier is a two byte value corresponding to the packet's source node's unique ID. The Destination Identifier is a two byte value corresponding to the packet's destination node's unique ID. The Payload Size is a one byte value equal to the payload's size in bytes. The Requirement Vector Identifier is 567 a one byte value which indicates the type (i.e., use case) 568 of the payload's data. The *Route* is a four byte array with 569 $N_{Source \ Identifier}$'s best route's values *i.e.*, energy, money, bit-570 rate and number of hops. The payload contains the data 571 shared by the source. It is a series of *n* bytes with *n* equal 572 to the header's Payload Size field. The trailer is a single 573 byte carrying the CRC8 Checksum of the header and pay-574 load parts. 575

576 8.3 Route construction

Let's consider the operations of node *i*. N_i boots up and starts the construction of its route matrix RM_i . RODENT accesses two sets of data: the link matrix LM_i and the set of route shared by N_i 's neighbors. N_i 's first step is to check LM_i for any link toward a base station *e.g.*, a Sigfox antenna or a LoRaWAN gateway. Such links are turned to single hop routes based on the links values from LM_i . Routes are stored in RM_i . N_i 's second step is to construct the routes passing through NBR(i)'s nodes. Let's consider the reception of a route from $NBR(i)_j$. N_i adds the received route's attributes to the attributes' values of the link L_{ii}^n . The resulting route R_{ii}^n is stored in RM_i .

8.4 Route selection

In classic WSN, route selection is trivial as the route with the lowest cost or rank is selected. In MTN, a route is a set of successive links, where each link may use a different RAT. Different RAT offers various performances and route selection in MTN have to take account of multiple criteria. We aim to support multiple use cases with different data requirements. Section 5 introduced RODENT's selection method. For node N_i , our lightweight TOPSIS takes as input the route matrix RM_i and a requirement vector RV_x relative to use case x. The selection outputs a ranking of the routes. The route coming out on top best fulfills the data requirements of use case x. For N_i , a best route BR_i^x is selected for every use case x.

601

603 8.5 Route propagation

Route propagation occurs through two mechanisms: pig-604 gybacking and control packets. Piggybacking allows 605 routes to be shared without dedicated transmissions. 606 Considering a RODENT packet carrying a data payload 607 of use case x, the header contains RV_x 's id number and 608 the best route BR_i^x . Wireless communications share a 609 common medium. Thus, N_{i} overhears every packet from 610 NBR(i), which allows N_i to update RM_i opportunisti-611 cally. If N_i stops overhearing route R_{ii}^x from its neigh-612 bor $NBR(i)_i$ e.g., because N_i is down, $R_{ii}^{x'}$ will timeout and 613 will be removed from RMi. To keep alive unused routes, 614 $NBR(i)_i$ will send dedicated control packets. Control pack-615 ets are regular packets with an empty payload. 616

617 9. PROTOCOL IMPLEMENTATION

Our implementation of RODENT is performed on Pycom
FiPy devices [21]. The specificity of FiPy devices is that
they offer five different RAT. These nodes take part in
the MTN and offload data to WiFi and LoRa base-stations
(BS). The hardware and firmware used are detailed in this
section.

624 9.1 Hardware

Pycom FiPy nodes are composed of WSN hardware: wire-625 less RAT, ESP32 CPU, few memory available which allows 626 ultra-low power usage. The available RAT are WiFi, LoRa, 627 Sigfox, LTE-M, NB-IoT and Bluetooth Low Energy (BLE). 628 Each RAT comes with different performances in terms of 629 energy consumption, economical cost, bit-rate, etc. RO-630 DENT performs route selection based on these character-631 istics. FiPy are coupled with Pytrack sensor shields which 632 provide an accelerometer, a GPS and a micro-USB port. 633 The LoRa BS is a B-L072Z-LRWAN1 board [22]. The WiFi 634 BS is an Edimax EW-7811Un dongle [23] connected to the 635 main computer. A Trip Lite U223-007 (7-Port USB Hub) 636

is used to connect every devices. The main computer is a
Dell Latitude 5590. It powers devices, collects and analyses results.

640 9.2 Firmware

A port of MicroPython available as firmware for the FiPy 641 allowed us to implement RODENT in Python. Upon boot, 642 a node N_i compute its unique ID. Based on LM_i it boots 643 up the needed RAT and constructs routes. The node is 644 then locked up in the main loop: i) select best route for 645 each RV_v, ii) add next payload to transmission buffer iii) 646 send every payload in buffer. Neighbor's route are added 647 in *RM*, upon reception. Neighbor's payload are appended 648 in the transmission buffer. Nodes print on the serial port 649 the characteristics of the packets sent. Upon the Pytrack's 650 button press, nodes switch between the two RV imple-651 mented: $RV_{monitoring}$ and RV_{alarm} . 652

The LoRa BS's firmware is implemented in C. It listens constantly for LoRa transmissions. Upon reception of a

Fig. 9 - Farm monitoring scenario.

RODENT packet, it is unpacked and its characteristics are
printed on the serial port. The WiFi BS is coded in Python.
It listens for RODENT WiFi transmissions, unpacks them
and prints characteristics on stdout.

10. RODENT EXPERIMENTS

To assess the performances of RODENT, we run experiments on real hardware. We configured the nodes to follow a specific scenario and measured the results. The experimental setup and scenario are presented in this section.

677

678

679

680

681

682

Aforementioned devices in Section 9 are connected to the main computer through the USB hub. Every node and BS are powered at the same time and boot up immediately. As we can see in Figure 8, every device is laying very close to each other. The main computer reads the stdout of the WiFi BS and the serial ports of the nodes and LoRa BS. Results are then computed off-line, post-experiment.

10.2 Scenario

We simulate a farm monitoring use case. Smart agriculture can help farmers in their everyday life, but farms are often an unfriendly environment for wireless sensors (large rural areas, tall crops...). MTN eases the technical difficulties by offering nodes multiple possibilities of communication (operator based networks, personal networks, multi-hop networks...). In our scenario, nodes are deployed throughout a field used for cultivating crops. The simulated setup is illustrated in Figure 9. Five nodes

Fig. 10 – Packet Delivery Ratio per node.

monitor environmental metrics useful for farmers. Nodes
have to offload numerical data on a regular basis while
saving up power. They may have to send an alarm if a
metric becomes off chart, putting the crops at risk (*e.g.*,
temperature).

Out of the five RAT available on FiPy, we are using WiFi, 688 LoRa and BLE in this scenario. Sigfox and LTE-M/NB-IoT 689 are not open technologies, so we could not use them di-690 rectly. LoRa and BLE links are more interesting in terms 691 of energetic savings than WiFi. Each node (Nx) is in a dif-692 ferent situation. N1 is the control node, it only has a WiFi 693 link with the WiFi BS. N2 can reach the WiFi BS and ben-694 efits from the LoRa link when RODENT is active. N3 have 695 to choose between reaching the WiFi BS directly at a high 696 energy cost or forwarding its data to its neighbor N1 via a 697 BLE link. *N*4 needs to be able to send regular monitoring 698 data as well as alarms, via WiFi or LoRa. N5 is an isolated 699 node, deployed too far away to directly communicate with 700 the WiFi BS. Farms are usually located in wide rural en-701 vironments, unfriendly to wireless waves because of tall 702 crops (e.g., corn). Thus white zones and isolated nodes 703 are common. Using RODENT, N5 can forward its data to 704 its neighbor N4 using LoRa. 705

We run three types of experiments. First, RODENT is not 706 active and nodes only use WiFi links, depicted in blue in 707 Figure 9. Second, RODENT is active, which allows nodes 708 to switch to LoRa and BLE links, depicted in red and green 709 in Figure 9. Third, RODENT is active, each LoRa mes-710 sage is sent two times and each BLE message is sent three 711 times, which increase the network's reliability. A video of 712 an experiment running is available online¹. 713

714 **11. EXPERIMENTAL RESULTS**

Topology and Packet Delivery Ratio (PDR) are measured.
Nodes transmit at an interval randomly picked in [2; 4]
seconds. We consider a population of 20 experiments
lasting 10 minutes each. Small population is sufficient

Fig. 11 - Energy consumption per RAT.

because of the low standard deviation. Longer experiments are not relevant because the network stabilizes after few messages exchanged. We do not directly compare RODENT's results to related works as the heavy difference between proposals makes it irrelevant, and increased flexibility cannot be measured. In this section we present the results obtained.

11.1 Topology

719

720

721

722

723

724

725

726

727

728

729

730

731

732

733

734

735

736

737

738

With the use of RODENT, the MTN's topology changes. N1 does not change its link because it can only reach the WiFi BS. N2 uses the LoRa link instead of the WiFi link, because it cost less energy. N3 decides to use the BLE link to offload its data to N1, which in turn forwards it to the WiFi BS. N4 offload its monitoring data to the LoRa BS, to reduce energy consumption compared to WiFi. It can still use the WiFi link to forward alarms, that needs a quicker RAT at the expense of higher energy cost. N5 is not isolated anymore, as it forwards its data to N4 through LoRa which will offload it to the LoRa BS in turn.

11.2 Packet Delivery Ratio

The Packet Delivery Ratio (PDR) is the ratio between the 739 total packets received and the total packets sent. The PDR 740 of every node taking part in the MTN is depicted in Fig-741 ure 10 along with its standard deviation. N1's PDR does 742 not changes, as its route remains the same. Without RO-743 DENT, N5's PDR is null as the node is isolated and can-744 745 not offload a single data packet. The PDR of N2, N4 and N5 is around 80% with RODENT which allows them to use 746 LoRa. It is not the same as WiFi because of frequent col-747 lisions, as nodes does not use a proper MAC. N3's PDR 748 is around 60% with RODENT. The node forwards its data 749 through BLE to N1. We achieved BLE raw transmissions 750 through the use of single BLE advertisements, hence the 751 packet loses. With the enhanced RODENT, we can see a 752 better PDR for all nodes, close to the one obtained with 753 only WiFi. 754

¹http://chercheurs.lille.inria.fr/bfoubert/ressources/ rodent.mp4

755 11.3 Energy consumption

Physical measurement of the Pycom FiPy's energy con-756 sumption is hazardous since it suffers from design prob-757 lems which lead to erroneous measurements [24]. We 758 choose to stick to the energy ratings given in the compo-759 nents data-sheets [17,21] to get a general idea, which are 760 showed in Figure 11. Compared to WiFi, BLE needs ap-761 proximately half-less current and LoRa a tenth. With the 762 Pycom FiPy's CPU, WiFi and BLE offers the same bit-rate. 763 LoRa's bit-rate is much slower leading to longer transmis-764 sion for a same amount of data. WiFi and BLE require a 765 heavier traffic control than LoRa does, which allows LoRa 766 to consume less energy. Thus, we can assume that RO-767 DENT enable significant energy savings. 768

769 12. CONCLUSION

WSN deployments are limited by the coverage and perfor-770 mances of the devices' RAT. The use of several RAT in an 771 MTN allow to overcome these shortcomings. In this arti-772 cle, we introduced the novel Routing Over Different Exist-773 ing Network Technologies protocol (RODENT). RODENT 774 is based on a lightweight TOPSIS method that reduces the 775 complexity of the computations and eliminates rank re-776 versal issues, lessening computation time of about 38%. 777 The resulting network interface selection is still similar 778 to the one obtained using classic TOPSIS in 82% of the ex-779 periments. 780 RODENT is designed for routing in MTN and enables the 781 use of multi-technologies routes. We demonstrate the fea-782 sibility and utility of MTN with a prototype network based 783 on a custom implementation of RODENT. Results show 784

that RODENT increase flexibility, reliability, energy sav ings and maintains a good PDR.

For future works, we plan to precisely measure energy 787 savings and extend RODENT to support downlink com-788 munications. This will further increase nodes' flexibility 789 and possibilities (*e.g.*, firmware over the air upgrade). We 790 plan to conceive an efficient link layer protocol for precise 791 link costs and performances assessment for multi-RAT. In 792 addition, we plan to combine RODENT with an efficient 793 data reduction scheme to reduce even more energy con-794 sumption. 795

Brandon Foubert received a Master's degree in Computer Networks and Embedded Systems from the University of Strasbourg in 2018. He investigated "Cooperation between multiple RPL networks" under the direction of Julien Montavont in the Network research group from the ICube laboratory. He is currently pursuing a PhD degree under the supervision of Nathalie Mitton in the FUN team at Inria Lille - Nord Europe since September 2018 and until September 2021. He is studying "Polymorphic wireless communication for connected agriculture".

Nathalie Mitton received the MSc and PhD. degrees in 896 Computer Science from INSA Lyon in 2003 and 2006 re-897 spectively. She received her Habilitation à diriger des 898 recherches (HDR) in 2011 from Université Lille 1. She 899 is currently an Inria full researcher since 2006 and from 900 2012, she is the scientific head of the Inria FUN team . Her 901 research interests focus on self-organization from PHY to 902 routing for wireless constrained networks. She has pub-903 lished her research in more than 50 international revues 904 and more than 120 international conferences. She is in-905 volved in the set up of the FIT IoT LAB platform (http: 906 //fit-equipex.fr, https://www.iot-lab.info), the 907 H2020 CyberSANE and VESSEDIA projects and in sev-908 eral program and organization committees such as In-909 focom (since 2019), PerCom 2020&2019, DCOSS (since 910 2019), Adhocnow (since 2015), ICC (since 2015), Globe-911 com (since 2017), Pe-Wasun 2017, VTC (since 2016), etc. 912 She also supervises several PhD students and engineers.
