Abstract
In this paper, we consider existential rules, an expressive formalism well suited to the representation of ontological knowledge and data-to-ontology mappings in the context of ontology-based data integration. The chase is a fundamental tool to do reasoning with existential rules as it computes all the facts entailed by the rules from a database instance. We introduce parallelisable sets of existential rules, for which the chase can be computed in a single breadth-first step from any instance. The question we investigate is the characterization of such rule sets. We show that parallelisable rule sets are exactly those rule sets both bounded for the chase and belonging to a novel class of rules, called pieceful. The pieceful class includes in particular frontier-guarded existential rules and (plain) datalog. We also give another characterization of parallelisable rule sets in terms of rule composition based on rewriting.

1 Introduction
Ontology-based data access (OBDA) systems aim at facilitating data querying through a conceptual layer formalized by an ontology (Poggi et al. 2008; Xiao et al. 2018). They rely on a three-level architecture comprising the ontology, the data sources and the mapping between the two. The key idea is that a user expresses queries at a conceptual level, and the data sources and the mapping are responsible for the translation of the query into facts. The system translates these queries into queries on the data via the mapping, while integrating existential reasoning.

When we abstract away from data sources and mappings, we obtain the fundamental ontology-based query answering problem, which takes as input an ontology $O$, an instance (or set of facts) $I$ and a (Boolean) conjunctive query $q$, both expressed in the vocabulary of $O$, and asks whether $I, O \models q$. Ontological knowledge is typically represented in description logics (e.g., (Baader et al. 2017; Bienvenu and Ortiz 2015)) or existential rules (e.g., (Cali, Gottlob, and Lukasiewicz 2009; Baget et al. 2009)) and we shall consider the latter language in this paper. Existential rules are an extension of first-order function-free Horn rules allowing for existentially quantified variables in the rule heads (e.g., $\forall x (s(x) \rightarrow \exists z \ t(x, z))$), which makes them able to infer the existence of unknown individuals. They generalise datalog and most description logics used to do reasoning on data, namely Horn description logics.

Two dual techniques are used to solve the ontology-based query answering problem: the chase, which enriches $I$ by performing a fixpoint computation with $O$ until a canonical model of $I$ and $O$ is obtained (then $q$ is asked on the result of the chase), and query rewriting, where $q$ is rewritten with $O$ into a query $q'$, such that for all instance $I$, holds $I, O \models q$ if and only if holds $I \models q'$. Query answering is undecidable with general existential rules, however there are expressive subclasses ensuring the termination of either technique.

In the OBDA paradigm, the instance $I$ is not materialized, but virtually defined by the mapping and the data. Precisely, an OBDA specification is given by an ontology $O$, a relational schema $S$ and a mapping $M$ from $S$ to $O$ (Lenzerini 2018). The mapping is itself composed of assertions of the form $q_S(x) \rightarrow q_O(x)$, where $q_S$ is a query on schema $S$ and $q_O$ is a conjunctive query on the vocabulary of $O$, both with tuple of answer variables $x$. When $q_S$ is also a conjunctive query, or a relational view, a mapping assertion can be seen as an existential rule. Then, the virtual instance $I_{(D,M)}$, associated with a database $D$ on $S$ and the mapping $M$, is the set of facts that would be obtained by chasing $D$ with $M$. Note that only a single (breadth-first) step of the chase is required here, as bodies and heads of mapping assertions are on disjoint sets of predicates. Since $I_{(D,M)}$ is virtual, an incoming query has to be rewritten, first with $O$, then with $M$, which yields a query directly asked on $D$. As rewriting is performed at query time, speeding up this process is a crucial issue. In particular, query rewriting with $O$ is a recursive process, which is not the case with $M$. For very lightweight ontology languages (the DL-Lite family or the W3C language RDFS), a practically efficient approach consists of compiling (part of) the ontological reasoning into the mapping, so that the rewriting step with $O$ can be avoided or drastically reduced (Kontchakov et al. 2014; Buron et al. 2020b). In these settings, each mapping assertion can be processed independently, the mapping head being enriched with knowledge it entails. Whether such technique can be extended to more expressive languages is an open issue, which motivated the work presented here.

Consider an OBDA setting where existential rules are used as a uniform language to express both the ontology and the mapping. Compiling ontological reasoning into the mapping can be seen as computing a new mapping $M'$ such that query rewriting with $O$ and $M$ is reduced to query rewriting with $M'$. From a dual viewpoint, for any database $D$, the instance $I_{(D,M')}$ is equivalent to the chase of $I_{(D,M)}$ with
such rule sets. Our main results are the following.

Example 1. Let $M = \{M_1, M_2\}$ and $O = \{R_1, R_2\}$, where $s_i$ and $t_i$ denote predicates from $S$ and $O$, respectively, and universal quantifiers are omitted:

- $M_1 = s_1(x, y) \rightarrow t_1(x, y)$
- $M_2 = s_2(x) \rightarrow t_2(x)$
- $R_1 = t_2(x) \rightarrow \exists z \ t_3(x, z)$
- $R_2 = t_1(x, y) \land t_3(x, z) \rightarrow t_4(y)$

Here, the ontology can be compiled into the mapping, which yields $M' = M \cup \{M_3, M_4\}$, where:

- $M_3 = s_2(x) \rightarrow \exists z \ t_3(x, z)$
- $M_4 = s_1(x, y) \land s_2(x) \rightarrow t_4(y)$.

Intuitively, $M'$ is obtained by composing the rules from $M \cup O$ until a fixpoint is reached (see Sect. 4), then keeping only mapping assertions, i.e., rules whose all body predicates are in $S$. We can check that, for any database $D$ on $S$, a single breadth-first step of the chase of $D$ with $M'$ suffices to produce the chase of $D$ with $M \cup O$.

With the aim of developing compilation techniques for OBDA systems based on existential rules, we asked ourselves the following question: under which conditions on the rules can the chase be simulated in a single step?

We formalize the desired property by the notion of parallelizable existential rule sets. Informally, a (finite) rule set $R$ is parallelizable if there exists a finite rule set $R'$ able to produce (an equivalent superset of) the chase of $R$ in a single breadth-first step, independently from any instance. The question we investigate in this paper is how to characterize such rule sets. Our main results are the following.

- Clearly, boundedness, which expresses that the number of chase steps is bounded independently from any instance, is a necessary condition for parallelisability. This notion has long been studied for datalog (Hillebrand et al. 1995) and more recently for existential rules (Bourhis et al. 2019; Delivorias et al. 2021). While boundedness is equivalent to parallelisability in the case of datalog, it does not ensure the parallelisability of an existential rule set. This leads us to define a new class of existential rules, namely pieceful. We show that parallelisable rule sets are exactly those sets that are both bounded and pieceful.

- The novel pieceful class has an interest in itself, as it generalizes datalog as well as a main class of existential rules, namely frontier-guarded, which itself covers some prominent description logics (see the last section for details).

- Piecefulness is based on the behavior of rules during the chase. Adopting the viewpoint of query rewriting, we study an operator of rule composition (that we call existential composition) based on so-called piece-unifiers, a notion at the core of rewriting with existential rules. We show that any bounded and pieceful rule set can be parallelized by a finite set of composed rules.

- This allows us to provide another characterization of pieceful rule sets based on their behavior during rule composition. Roughly, a certain property (that we call existential stability) has to be fulfilled by every pair of rules of the set and preserved whenever composed rules are added to the set.

- Finally, noting that rule composition does not fit well with the behavior we intuitively expected, we introduce another rule composition operator (that we call compact composition). The result of this operator goes beyond the existential rule language. We show however that, when the stability property is satisfied, both kinds of compositions yield logically equivalent formulas.

We believe that these results open up many practical and theoretical perspectives, which we discuss in the last section. Full proofs that could not be included due to space restrictions are available in a technical report (Buron, Mugnier, and Thomazo 2021).

2 Preliminaries

Generalities. A vocabulary is a pair $\mathcal{V} = (\mathcal{P}, \mathcal{C})$, where $\mathcal{P}$ is a finite set of predicates and $\mathcal{C}$ is a possibly infinite set of constants. A term on $\mathcal{V}$ is a constant from $\mathcal{C}$ or a variable. An atom on $\mathcal{V}$ has the form $p(t)$ where $p \in \mathcal{P}$ is a predicate of arity $n$ and $t$ is a tuple of terms on $\mathcal{V}$ with $|t| = n$. An atom is ground if it has no variable. Given an atom or set of atoms $S$, we denote by $\text{var}(S)$, $\text{const}(S)$ and $\text{term}(S)$ its sets of variables, constants and terms, respectively. We will often see a tuple $x$ of pairwise distinct variables as a set. We denote by $|=\vdash$ the classical logical consequence. Given two sets of atoms $S_1$ and $S_2$, a homomorphism $h$ from $S_1$ to $S_2$ is a substitution of $\text{var}(S_1)$ by $\text{term}(S_2)$ such that $h(S_1) \subseteq S_2$ (we say that $S_1$ maps to $S_2$ by $h$).

Instances and Rules. An instance is a finite set of ground atoms. Any finite set of atoms $S$ can be turned into an instance, denoted by freeze$(S)$, by freezing its variables, i.e., bijectively renaming each variable by a fresh constant. An extended instance is a (possibly infinite) set of atoms, in which variables are classically called nulls. The associated (possibly infinite) formula is the existential closure of the conjunction of the atoms. An existential rule $R$ (or simply rule hereafter) is a closed formula of the form

$$\forall x \exists y \ [ B(x, y) \rightarrow \exists z \ H(x, z) ]$$

where $B$ and $H$ are non-empty and finite conjunctions of atoms on variables, respectively called the body and the head of the rule, denoted by body$(R)$ and head$(R)$, and $x, y$ and $z$ are pairwise disjoint. We make the common assumption that rules do not contain constants, which simplifies technical tools. The set $x$ is called the frontier of $R$ and is denoted by $\text{fr}(R)$. Its elements are called frontier variables. The set $z$ is called the set of existential variables (of $R$) and is denoted by $\text{exist}(R)$. An existential rule $R$ is datalog if $|\text{head}(R)| = 1$ and $\text{exist}(R) = \emptyset$. For brevity, we often denote by $B \rightarrow H$ a rule with body $B$ and head $H$. In the following, we denote by $\mathcal{R}$ a finite set of existential rules and assume w.l.o.g. that distinct rules in $\mathcal{R}$ have disjoint sets of variables. In our examples, we reuse variables for simplicity.

A rule $R = B \rightarrow H$ is applicable to a set of atoms $S$ if there is a homomorphism $\pi$ from $B$ to $S$. The pair $(R, \pi)$ is called a trigger for $S$. The application of $R$ according to $\pi$ (or: of the trigger $(R, \pi)$) produces a set of atoms obtained from head$(R)$ by replacing each frontier variable $x$
with $\pi(x)$ and each existential variable with a fresh variable, called a null. We denote by $\pi^{\text{safe}}$ this extension of $\pi$ that "safely" renames existential variables; hence, atoms produced by distinct applications of the same rule have disjoint sets of nulls. The set of atoms resulting from the application of $(R, \pi)$ to $S$ is $\alpha(S, R, \pi) = S \cup \pi^{\text{safe}}(H)$.

An $R$-derivation (from $I$ to $I'$) is a finite sequence $(I_0 = I, (R_1, \pi_1, I_1), \ldots, (R_k, \pi_k, I_k))$ such that for all $0 < i \leq k$, $R_i \in \mathcal{R}$, $(R_i, \pi_i)$ is a trigger for $I_{i-1}$ and $I_i = \alpha(I_{i-1}, R_i, \pi_i)$. When only the successive (extended) instances are needed, we note $(I_0 = I, I_1, I_2, \ldots)$. Chase. The chase builds a derivation from an instance by repeatedly applying rules until a fixpoint is reached. We rely on the semi-oblivious chase variant (in short, so-chase), in which two triggers $(R, \pi_1)$ and $(R, \pi_2)$ that coincide on the frontier of $R$ produce exactly the same result (Marnette 2009). More precisely, we assume that nulls are named as follows: given a trigger $(R, \pi)$, for all $z \in \text{exist}(R)$, $\pi^{\text{safe}}(z) = z_{(R, \pi_0(I))}$, where $\pi_0(I)$ denotes the restriction of $\pi$ to the domain $\text{fr}(R)$. Hence, the name of a null created by a trigger $(R, \pi)$ is based on $R$ and $\pi_0(I)$, but $\pi$ itself. We consider a breadth-first so-chase defined as follows: $\text{chase}_0(I, R) = I$ and, for any $i > 0$,

$$\text{chase}_{i+1}(I, R) = \text{chase}_i(I, R) \cup \bigcup_{(R, \pi)} \{\pi^{\text{safe}}(\text{head}(R))\}$$

where $(R, \pi)$ is any trigger for $\text{chase}_{i-1}(I, R)$ and for any $z \in \text{exist}(R)$, $\pi^{\text{safe}}(z) = z_{(R, \pi_0(I))}$. Finally, $\text{chase}_\infty(I, R) = \bigcup_{i \geq 0} \text{chase}_i(I, R)$.

Example 2. Let $I = \{p(a, b)\}$ and $R = \{p(x, y) \rightarrow \exists z. p(x, z) \land A(z)\}$. By the trigger $t_1 = (R, \{x \mapsto a, y \mapsto b\})$, we obtain $\text{chase}_1(I, R) = \{p(a, b), p(a, \nu), A(\nu)\}$ with $\nu = z_{(R, \text{fr}(a))}$. The trigger $t_2 = (R, \{x \mapsto a, y \mapsto \nu\})$ then produces the same atoms as $t_1$. Finally, $\text{chase}_\infty(I, R) = \text{chase}_1(I, R)$.

Query Answering. A conjunctive query (CQ) is of the form $q(x) = \exists y \varphi(x, y)$, where $x$ and $y$ are disjoint tuples of variables, $\varphi$ is a conjunction of atoms, and $x \cup y = \text{var}(\varphi)$; the free variables in $\varphi$ (i.e., $x$) are called answer variables. A Boolean CQ has no free variables. A union of conjunctive queries (UCQ) is a disjunction of CQs that have the same arity $[x]$. An (extended) instance $I$ answers positively to a Boolean CQ $q$ iff $I \models q$. More generally, a tuple of constants $c$ is an answer to a CQ $q(x)$, with $[x] = [c]$, on $I$ if $I \models q[c]$, where $q[c]$ is obtained by substituting the ith-variable in $x$ by the ith-constant in $c$. The CQ answering problem takes as input an instance $I$, a rule set $\mathcal{R}$, a query $q(x)$ and a tuple of constants (c), with $[x] = [c]$, and asks whether $I, \mathcal{R} \models q[c]$. It holds that $I, \mathcal{R} \models q[c]$ iff there is an $\mathcal{R}$-derivation from $I$ to $I'$ such that $I' \models q[c]$. Equivalently, $I, \mathcal{R} \models q[c]$ iff there is $k$ such that $\text{chase}_k(I, \mathcal{R}) \models q[c]$.

Pieces. The notion of piece is key in this paper. Given a set of atoms $S$, a piece of $S$ with respect to a set of terms $T$ is a non-empty set $S' \subseteq S$ such that (1) for any atom $a \in S'$, if $a$ shares a term from $T$ with some atom $a' \in S'$, then $a \in S'$, and (2) there is no strict subset of $S'$ that satisfies (1), i.e., $S'$ is minimal. Intuitively, atoms of $S$ are glued together by the terms of $T$, which yields pieces. Note that, for any set of atoms $S$ and set of terms $T$, $S$ can be partitioned into pieces w.r.t. $T$. Here, pieces are defined with respect to existential variables or to nulls, depending on the considered objects. By default, a piece of $S$ is w.r.t. exist($S$) if $S$ is a rule head and w.r.t. the nulls in $S$ if $S$ is an (extended) instance.

A rule is called single-piece if its head forms a single piece. Any rule can be decomposed into a (trivially) equivalent set of single-piece rules. For instance, a rule $r(x,y) \rightarrow \exists z_1 \exists z_2 p(x, z_1) \land A(z_1) \land A(z_2) \land p(x, y)$ has a head with three pieces: $\{p(x, z_1), A(z_1)\}$, $\{A(z_2)\}$ and $\{p(x, y)\}$, hence can be decomposed into three single-piece rules: $r(x,y) \rightarrow \exists z_1 p(x, z_1) \land A(z_1)$, $r(x,y) \rightarrow \exists z_2 A(z_2)$ and $r(x,y) \rightarrow p(x, y)$. In the following, we assume that rules are single-piece. This assumption simplifies our setting, although all notions and results of this paper could be reformulated without making it.

Piece-Unifiers. Piece-unifiers are a generalization of classical unifiers that take care of existential variables in rule heads by unifying sets of atoms instead of single atoms (Baget et al. 2009). Query rewriting as well as rule composition (see Sect. 4) are based on this notion. In the definition below, we give a simplified version of piece-unifiers, which does not take constants into account. See, e.g., (König et al. 2015) for details about piece-unifiers.

Given sets of atoms $S$ and $S' \subseteq S$, the set of separating variables in $S'$ w.r.t. $S$, denoted by $\text{sep}_S(S')$, is the set of variables that belong to both $S'$ and $S \setminus S'$. Note that when $S'$ is a piece of an extended instance $I$, $\text{sep}_S(S')$ is necessarily empty (as $S'$ shares only constants with the rest of $I$).

Definition 1 (Piece-unifier). Let $S$ be a set of atoms and $R = B \rightarrow H$ be a rule (both without constants) such that $\text{var}(S) \cap \text{var}(B \cup H) = \emptyset$. A piece-unifier of $S$ with $R$ (or with $H$) is a triple $\mu = (S', H', u)$ with $S' \neq \emptyset$, $S' \subseteq S$, $H' \subseteq H$, and $u$ is a substitution of $\text{fr}(R) \cup \text{var}(S')$ by $\text{var}(\text{head}(R))$ such that:

1. For all $x \in \text{fr}(R)$, $u(x) \in \text{fr}(R)$
2. For all $x \in \text{sep}_S(S')$, $u(x) \in \text{fr}(R)$
3. $u(S') = u(H')$.

Let $S$ be a set of atoms and $\mu = (S', H', u)$ be a piece-unifier of $S$ w.r.t. $R : B \rightarrow H$. The (direct) rewriting of $S$ w.r.t. $\mu$ is $\beta(S, R, \mu) = u(B) \cup u(S')$. An $R$-rewriting $S_0$ of $S$ is obtained by a finite sequence $(S_0 = S, S_1, \ldots, S_k)$ such that, for all $0 < i \leq k$, $S_i$ is a direct rewriting of $S_{i-1}$ w.r.t. a piece-unifier of $S_{i-1}$ with (a copy of) a rule from $R$.

Example 3 (Piece-Unifier). Let $R = A(x) \rightarrow \exists y. p(x, z)$ and $S_0 = \{p(w, v), B(v)\}$. There is no piece-unifier of $S_1$ with $R$ since $v$ is a separating variable of $S_1 = \{p(w, v), B(v)\}$, hence cannot be unified with $z$. Let $S_2 = \{p(w_1, v), B(w_1), p(w_1, v), C(w_2)\}$. The triple $\mu = (S_2', H', u)$ with $S_2' = \{p(w_1, v), p(w_1, v)\}$, $H' = \{p(x, z)\}$ and $u = \{w_1, w_2 \mapsto x, v \mapsto z\}$ is a piece-unifier of $S_2$ with $R$, which yields the direct rewriting $\{A(x), B(c(x))\}$.

A fundamental property of piece-unifiers is the following: given any instance $I$, rule set $\mathcal{R}$ and Boolean CQ $q$, there
is an $R$-derivation from $I$ to an $I_i$ such that $q$ maps to $I_i$ ($I_i \models q$) iff there is an $R$-rewriting $q'$ of $q$ such that $q'$ maps to $I$ ($I \models q'$). Note that this property does not rely on rules being single-piece.

**Fundamental Properties of Rule Sets.** A rule set $\mathcal{R}$ is *so-chase finite* if for any instance $I$, there is $k$ such that chase$_k(I, \mathcal{R})$ is chase$_{\infty}(I, \mathcal{R})$. A rule set $\mathcal{R}$ is a *finite unification set* (fus) if for any Boolean CQ $q$, there is a finite set $Q$ of $R$-rewritings of $q$, such that for any $R$-rewriting $q'$ of $q$, there is $q'' \in Q$ that maps to $q'$ (Baget et al. 2009). It is not hard to see that fus is equivalent to first-order rewritability (introduced in (Calvaneo et al. 2007)): $\mathcal{R}$ is first-order rewritable if for any Boolean CQ $q$, there is a UCQ $Q$, such that for any instance $I$, it holds that $I, \mathcal{R} \models q$ iff $I \models Q$. Moreover, as several times remarked, fus is equivalent to the *bounded derivation depth property* (Cali, Gottlob, and Lukasiewicz 2009): for any Boolean CQ $q$, there is $k$ such that for any instance $I$, if $I, \mathcal{R} \models q$ then chase$_k(I, \mathcal{R}) \models q$. Finally, a rule set is *so-bounded* if there is $k$ (a bound) such that for any instance $I$, chase$_k(I, \mathcal{R}) = \text{chase}_{\infty}(I, \mathcal{R})$ (Delivoria et al. 2021). Clearly, when a rule set is so-bounded, it is also so-chase finite and fus. The reciprocal holds true for single-piece rules (follows from (Bourhis et al. 2019)). In the remaining, we will simply write chase and bounded in place of so-chase and so-bounded.

**Example 4.**
\[ \mathcal{R}_1 = \{ A(x) \rightarrow \exists z \ p(x, z) \land A(z) \} \] is fus and not chase-finite.\[ \mathcal{R}_2 = \{ R_1 : p(x, y) \land p(y, z) \rightarrow p(x, z) \} \] is a datalog (hence chase-finite) and not fus (hence not bounded).\[ \mathcal{R}_3 = \mathcal{R}_2 \cup \{ R_2 : p(x, y) \land p(u, z) \rightarrow p(x, z) \} \] is bounded derivation depth property (Cali, Gottlob, and Lukasiewicz 2009).

**Note on this definition.** A more powerful notion of parallelisability could be obtained by dropping the injectivity requirement in Point 1. Then, chase$_1(I, \mathcal{R}')$ would be equivalent to chase$_{\infty}(I, \mathcal{R})$ but would not necessarily include it. This notion could also be obtained without changing the definition but considering a stronger chase variant for chase$_{\infty}(I, \mathcal{R})$, namely the *core chase*, which produces a minimal canonical model of $I, \mathcal{R}$ (Deutsch, Nash, and Remmel 2008). However, the core chase is not monotonic and its result may even not be obtainable by any $R$-derivation. We have chosen here to consider the well-behaved so-chase.

**Proposition 1.** If $\mathcal{R}$ is parallelisable, then it is bounded.

**Proof.** Let us assume that $\mathcal{R}$ is parallelised by $\mathcal{R}'$. For any instance $I$, chase$_1(I, \mathcal{R}')$ is finite because $\mathcal{R}'$ is finite. As there is an injection from chase$_{\infty}(I, \mathcal{R})$ to chase$_1(I, \mathcal{R}')$, chase$_{\infty}(I, \mathcal{R})$ is finite. Now, for each rule $R \in \mathcal{R}'$, let $I = \text{freeze}$(body($R$)): since $\mathcal{R}$ is applicable to $I$ and chase$_1(I, \mathcal{R}')$ maps to chase$_{\infty}(I, \mathcal{R})$, there is $k_R$ such that head($R$) maps to chase$_{k_R}(I, \mathcal{R})$. Let $k$ be the maximum $k_R$ over all rules $R \in \mathcal{R}$. For any instance $I$, there is $n$ such that chase$_{\infty}(I, \mathcal{R}) = \text{chase}_n(I, \mathcal{R})$ with $n \leq k$. Hence, $\mathcal{R}$ is bounded by $k$.

The converse is however not true, as witnessed by the following example.

**Example 5 (Prime Example).** Let $\mathcal{R} = \{ R_1, R_2 \}$ where:
\[ R_1 : A(x) \rightarrow \exists z \ p(x, z) \]
\[ R_2 : p(x, z) \land B(y) \rightarrow r(z, y) \]
\( \mathcal{R} \) is bounded but not parallelisable. Let, for any $n$, $I_n = \{ \text{A}(a), B(b_1), \ldots, B(b_n) \}$. There is a null in chase$_{\infty}(I_n, \mathcal{R})$ that appears in $n+1$ atoms (apply $R_1$, once, which creates a null, then apply $R_2$ $n$ times). Hence, there is no finite set of rules $\mathcal{R}'$ such that chase$_{\infty}(I_n, \mathcal{R})$ injectively maps to chase$_1(I, \mathcal{R}')$ for any $n$.

Motivated by this example, we now introduce a new class of rules, called *pieceful*.

### 3.2 The Pieceful Class

In short, pieceful rule sets ensure that for any rule application, the entire rule frontier is mapped either to terms from the initial instance or to terms that occur in atoms brought by a single previous rule application.

**Definition 3 (Pieceful Derivation).** An $R$-derivation $(I_0 = I), I_1, \ldots, I_k$, is pieceful if for all $i$ with $0 < i \leq k$, either $\pi_i(\text{fr}(R_{i})) \subseteq \text{term}(I)$ or there is $j < i$ such that $\pi_j(\text{fr}(R_{j})) \subseteq \text{term}(A_j)$, where $A_j = \pi_j^{\text{ale}}(\text{head}(R_{j}))$.

**Definition 4 (Pieceful Rule Set).** A rule set $\mathcal{R}$ is pieceful if (for any instance $I$) any $R$-derivation (from $I$) is pieceful.

**Example 6.** Consider again Example 5. From $I = \{ \text{A}(a), B(b) \}$, one builds a non-pieceful derivation $(I_0 = I)(R_1, \pi_1, I_1)(R_2, \pi_2, I_2)$. Indeed, $(R_1, \pi_1)$ produces $\pi_1^{\text{ale}}(\text{head}(R_1)) = A_1 = \{ \text{A}(a, v_0) \}$, with $v_0$ the null created from $z$. Then, $\pi_2 = \{ x \mapsto a, y \mapsto b, z \mapsto v_0 \}$. Since fr($R_2$) = $\{ y, z \}$ is mapped to $\{ b, v_0 \}$, with $b \not\in \text{term}(A_1)$ and $v_0 \not\in \text{term}(I)$, this derivation is not pieceful, hence neither is $\mathcal{R}$.
Interestingly, when a rule set is not pieceful, it is possible to build instances that generalize the situation from Example 5, so that the chase creates nulls that occur in an arbitrarily large number of atoms, as shown by next Proposition 2. As will become clear later (Proposition 5), the reciprocal statement is true when the rule set is chase-finite.

**Proposition 2.** If \( \mathcal{R} \) is not pieceful then, for all \( n \), there exist an instance \( I_n \) and a null \( \nu_n \) such that \( \nu_n \) occurs in at least \( n \) atoms in \( \text{chase}_\infty(I_n, \mathcal{R}) \).

**Proof.** (Sketch) Let \( I^0, \ldots, I^{n-1}, I^n \) be a non-pieceful derivation such that \( I^0, \ldots, I^{n-1} \) is pieceful, i.e., \( (R_n, \pi_n) \) applied on \( I^{n-1} \) is the first application that violates the pieceful condition. From that derivation, we build a set of instances \( \{I_i\} \) such that the chase of \( I_i \) contains a null that occurs in at least \( i \) (distinct) atoms.

At least one frontier variable of \( R_n \) is mapped to a null. Let \( k \) be the largest integer such that \( (R_k, \pi_k) \) introduces a null (in \( I^k \)) to which a frontier variable of \( R_n \) is mapped by \( \pi_n \). Let \( \nu^* \) be this null. We define by induction on \( i \) the instance \( I_i \) as follows, where each \( f_i(I^{k-1}) \) denotes a freezing of \( I^{k-1} \): (i) \( I_0 = f_0(I^{k-1}) \) and (ii) for any \( i \geq 1 \), \( I_i = I_{i-1} \cup f_i(I^{k-1}) \) where: if \( x \in \pi_k(\text{fr}(R_k)) \), then \( f_i(x) = f_0(x) \), otherwise \( f_i(x) \) is a fresh constant (w.r.t. the whole construction). Intuitively, \( I_i \) is built from \( i + 1 \) copies of \( I^{k-1} \), where all the terms have been freshly renamed except for those in \( \pi_k(\text{fr}(R_k)) \). From any \( I_i \), we can build a derivation that mimics the initial derivation \( I^{k-1}, \ldots, I^n \) and show that \( \nu^* \) occurs in \( i + 1 \) atoms.

It follows that any parallelisable set is pieceful:

**Proposition 3.** If \( \mathcal{R} \) is parallelisable, then it is pieceful.

**Proof.** Assume that \( \mathcal{R} \) is parallelisable by \( \mathcal{R}' \). Notice that for any \( I \), any null in \( \text{chase}_\infty(I, \mathcal{R}) \) occurs in at most \( h \) atoms, where \( h \) is the maximal size of a rule head in \( \mathcal{R}' \) (indeed, two distinct rule applications from \( \mathcal{R}' \) cannot share any null). Since \( h \) is bounded independently from \( I \), by contraposite of Proposition 2, \( \mathcal{R} \) is pieceful.

How does the pieceful class fit in the existential rule landscape? Clearly, pieceful rule sets are greedy-bounded-treewidth sets (gbts) (Baget et al. 2011b; Rudolph et al. 2014), an expressive family for which CQ answering is decidable. The gbts class includes some prominent existential classes, see Figure 1. There are three basic classes: (plain) datalog (e.g., (Abiteboul, Hull, and Vianu 1994)), in which there are no existential variables at all; guarded rules, in which all the variables from a rule body are guarded, i.e., jointly occur in a body atom (Cali, Gottlob, and Lukasiewicz 2009; Cali, Gottlob, and Kifer 2013); frontier-one rules, in which the frontier of a rule is restricted to (at most) one variable (Baget et al. 2009). Combining guardedness and frontier-based restrictions leads to frontier-guarded rules, in which only the frontier of a rule needs to be guarded (Baget, Leclère, and Mugnier 2010). The guardedness condition is further relaxed in weakly (frontier) guarded (wfg) rules, in which only the (frontier) variables possibly mapped to nulls during the chase need to be guarded.

As pictured in Figure 1, the pieceful class includes datalog and frontier-guarded, but not wfg (Example 5 is wfg) and it is not difficult to see that it is actually incomparable with wfg.

**Proposition 4.** Any set of frontier-guarded existential rules or of datalog rules is pieceful.

### 3.3 Characterizing Parallelisability

We first point out that the chase of any instance \( I \) is equal to the union of its pieces (w.r.t. nulls). A fundamental property of pieceful rules is that the application of a rule \( B \rightarrow H \) at level \( i \) can never connect two pieces of \( \text{chase}_{i-1}(I, \mathcal{R}) \); when it does not produce an atom already present in \( \text{chase}_{i-1}(I, \mathcal{R}) \), either it creates a new piece of size \( |H| \) (when the frontier is mapped to terms from \( I \)), or it makes an existing piece grow by \( |H| \) atoms (when the frontier is mapped to terms with at least one null).

**Proposition 5.** If \( \mathcal{R} \) is pieceful then for any instance \( I \) and integer \( k \), the maximal size of a piece in \( \text{chase}_k(I, \mathcal{R}) \) is bounded independently from \( I \).

**Proof.** (Sketch) Given \( I \) and \( \mathcal{R} \), we note \( P(i) \) the maximal size of a piece in \( \text{chase}_i(I, \mathcal{R}) \). We prove that \( P(0) = 1 \) and, for \( i \geq 0, P(i+1) \leq (P(i) \times a)^{fr} \times h \times |\mathcal{R}| \), where \( a \) is the maximal arity of a predicate, \( fr \) and \( h \) are the maximal size of a rule frontier in \( \mathcal{R} \) and a rule head in \( \mathcal{R} \), respectively.

**Corollary 1.** If \( \mathcal{R} \) is pieceful and bounded, then for any instance \( I \), the maximal size of a piece in \( \text{chase}_\infty(I, \mathcal{R}) \) is bounded independently from \( I \).

![Figure 1: The gbts classes ordered by syntactic inclusion (and the data complexity of the associated Boolean CQ answering problem)](image)
Based on this corollary, we are now able to show that any bounded pieceful set is parallelisable. We will give another proof of this result in Sect. 4 (see Cor. 2).

**Proposition 6.** If $\mathcal{R}$ is pieceful and bounded then it is parallelisable.

**Proof.** (Sketch) As $\mathcal{R}$ is pieceful and bounded, there is a finite set of pieces $\mathcal{P}$ such that for any instance $I$, any piece of chase$(I, \mathcal{R})$ is isomorphic to a piece of $\mathcal{P}$. By isomorphism from a piece $P_1$ to a piece $P_2$, we mean a bijection $b$ from term$(P_1)$ to term$(P_2)$ such that, for all $x \in$ term$(P_1)$, $b(x)$ is a null if $x$ is a null, and $b(P_1) = P_2$.

For any piece $P \in \mathcal{P}$, let $(cp)$ be a tuple obtained by a total ordering on const$(P)$, and consider the query $q_P(cp) = \exists y P(cp, y)$, with $y$ denoting the variables from $P$. Let $Q_P$ be a finite complete set $\mathcal{R}$-rewritings of $q_P$ (note that we need here the general definition of piece-unifiers that deals with constants). There is such set for any $P$, as $\mathcal{R}$ is bounded, hence $fus$. We define $\mathcal{R}'$ as the set of rules of the shape $q_P'(x) \rightarrow \exists y P(x, y)$, where $x$ is a tuple of variables in bijection with $cp$, for $P \in \mathcal{P}$ and $q_P' \in Q_P$. $\square$

From Propositions 1, 3 and 6, we finally obtain the following characterization of parallelisability:

**Theorem 1.** A rule set is parallelisable if and only if it is both bounded and pieceful.

### 4 Parallelisability and Rule Composition

Early work on datalog has shown that a datalog rule set $\mathcal{R}$ is ‘parallelisable’ (according to our definition) if and only if it is bounded (see, e.g., (Graff et al. 1993)). Moreover, such set, say $\mathcal{R}^*$, can be computed by an operation called unfolding: given rules $R_1 : B_1 \rightarrow H_1$ and $R_2 : B_2 \rightarrow H_2$, and a (most general) unifier $u$ of an atom $A$ in $B_2$ with the atom in $H_1$, the unfolding of $R_2$ by $R_1$ is the rule $u(B_1) \rightarrow u(B_2 \setminus \{A\}) \rightarrow u(H_2)$; starting from $\mathcal{R}$, on can build $\mathcal{R}^*$ by repeatedly unfolding a rule from $\mathcal{R}^*$ by a rule from $\mathcal{R}$, until a fixpoint is reached. This is illustrated by the next example.

**Example 7 (Datalog Unfolding).** Let $\mathcal{R} = \{R_1, R_2, R_3\}$ with:

- $R_1 : A(x) \rightarrow B(x)$
- $R_2 : C(x) \rightarrow D(x)$
- $R_3 : B(x) \land D(x) \rightarrow G(x)$

Denoting $R_i \circ R_j$ the unfolding of $R_i$ by $R_j$, we obtain:

- $R_3 \circ R_1 : A(x) \land D(x) \rightarrow G(x)$
- $R_3 \circ R_2 : C(x) \land B(x) \rightarrow G(x)$
- $R_3 \circ R_1 \circ R_2 : A(x) \land C(x) \rightarrow G(x)$
- $R_3 \circ R_2 \circ R_2 : B(x) \land D(x) \rightarrow G(x)$
- $R_3 \circ R_1 \circ R_1 \circ R_2 = (R_3 \circ R_1) \circ R_2$

Finally, $\mathcal{R}^* = \mathcal{R} \cup \{R_3 \circ R_1, R_3 \circ R_2, (R_3 \circ R_1) \circ R_2\}$. Here $\mathcal{R}^*$ is finite, as $\mathcal{R}$ is bounded.

In the following, we will consider composition of existential rules, which generalizes this notion of unfolding.

#### 4.1 Rule Composition

Composition of existential rules has been exploited as a means of tracing ‘chained’ sequences of rule applications (e.g., (Baget et al. 2014; Wang, Wang, and Zhang 2018)). It is naturally based on the notions of piece-unifier and rewriting. The next definition of rule composition furthermore takes pieces into account.

**Definition 5 (Rule Composition).** Given rules $R_1 : B_1 \rightarrow H_1$ and $R_2 : B_2 \rightarrow H_2$ on disjoint sets of variables, and $\mu = (\{H'_2, u\})$ a piece-unifier of $B_2$ with $R_1$, the (existential) composition of $R_2$ with $R_1$ w.r.t. $\mu$ is the following existential rule, denoted by $R_2 \circ_\mu R_1$, or simply $R_2 \circ R_1$:

1. If $u(fr(H'_2)) \cap \exists \text{exist}(R_1) = \emptyset$:
   
   $R_2 \circ_\mu R_1 = u(B_1) \cup u(B_2 \setminus B'_2) \rightarrow u(H_2)$

2. Otherwise:
   
   $R_2 \circ_\mu R_1 = u(B_1) \cup u(B_2 \setminus B'_2) \rightarrow u(H_1) \cup u(H_2)$

Note that $u(B_1) \cup u(B_2 \setminus B'_2)$ is exactly the rewriting of $B_2$ w.r.t. $\mu$.

The first case in the definition is when no frontier variable from $R_2$ is unified with an existential variable from $R_1$, i.e., $u(fr(H'_2)) \subseteq fr(R_1)$. Then, defining $R_2 \circ_\mu R_1$ as in Point 2 would lead to a rule with a two-piece head (resp., $u(H_1)$ and $u(H_2)$), which can be decomposed into two single-piecehead rules. Moreover, the rule $u(B_1) \cup u(B_2 \setminus B'_2)$ is useless because every application of this rule can be obtained with an application of $R_1$. In the second case, since at least one frontier variable from $B'_2$ is unified with an existential variable from $R_1$, $u(H_1) \cup u(H_2)$ forms a single piece. Therefore, restricting the rule head to $u(H_2)$ would result in a loss of information. Note that in both cases, the obtained rule $R_2 \circ R_1$ has a single piece head.

**Example 8.** Let $\mathcal{R}$ contain three rules:

- $R_1 : A(x) \rightarrow \exists z p(x, z)$
- $R_2 : p(x, z) \rightarrow B(z)$
- $R_3 : C(x) \land B(y) \rightarrow r(x, y)$

The composed rule $R_3 \circ R_2 = p(x', z) \land C(x) \rightarrow r(x, z)$ illustrates Point 1. Defining $R_3 \circ R_2$ as in Point 2 would lead to the following rule with a two-piece head:

$p(x', z) \land C(x) \rightarrow B(z) \land r(x, z)$

We can see that $p(x', z) \land C(x) \rightarrow B(z)$ is useless w.r.t. $R_2$. $R_3 \circ R_1 = A(x) \rightarrow \exists z p(x, z) \land B(z)$ illustrates Point 2.

The set $\mathcal{R}^*$ includes the original set $\mathcal{R}$ as well as all rules obtained by composition.

**Definition 6.** ($\mathcal{R}^*$) The set of (existentially-) composed rules associated with $\mathcal{R}$, denoted by $\mathcal{R}^*$, is the possibly infinite set inductively defined as follows:

- (base) $\mathcal{R} \subseteq \mathcal{R}^*$,
- (induction) if $R_i, R_j \in \mathcal{R}^*$ and there is a piece-unifier $\mu$ of body$(R_i)$ with $R_j$, then $R_i \circ_\mu R_j \in \mathcal{R}^*$.

$\mathcal{R}^*$ is sound and complete in the sense that entailment of Boolean CQs is preserved (with $\mathcal{R}^*$ applied in a single breadth-first step). Formally: for any rule set $\mathcal{R}$, instance $I$ and Boolean CQ $q$, holds $I, \mathcal{R} \models q$ if and only if holds chase$_I(\mathcal{R}^*, \models) \models q$. Soundness relies on the fact that all the rules in $\mathcal{R}^*$ are entailed by $\mathcal{R}$ and completeness follows from (Wang, Wang, and Zhang 2018), Prop. 2.

The next proposition yields a more specific completeness result: if $\mathcal{R}$ is a pieceful rule set, then for any instance $I$, each piece of chase$_\infty(I, \mathcal{R})$ can be obtained by applying a rule from $\mathcal{R}^*$ to $I$. 

Proposition 7. Let I be an instance and \( R \) be a set of rules. For any pieceful derivation of length \( i \) resulting in \( I \), for any piece \( P \) in \( I \), either \( P \subseteq I \) or there exist a rule \( R^* \in R^* \) and a homomorphism \( \pi \) from \( \text{body}(R^*) \) to \( I \) such that \( P \) maps to \( \pi^\text{safe}(\text{head}(R^*)) \) by an injective homomorphism.

Proof. (Sketch) We prove the result by induction on the length \( i \) of the derivation. For \( i = 1 \), if \( P \not\subseteq I \), then \( P \) has been generated by an application of a rule from \( R \in R \subseteq R^* \). Assuming that the result holds for any piece \( P \) of \( I \), then we show it also holds for any piece \( P \) of \( I \). Let \( I_0, (R_1, \pi_1, I_1), \ldots, (R_k, \pi_k, I_k) \) be a derivation of length \( i \). The body of \( R_i \) is mapped by \( \pi_i \) to \( k \) pieces of \( I_{i-1} \), where \( k \leq |\text{var}(\text{body}(R_i))| \). Let \( P \) be the piece created or completed by the application of \( R_i \) by \( \pi_i \). As the derivation is pieceful, \( P \) is either a piece of \( I_{i-1} \) to which \( \pi_i^\text{safe}(\text{head}(R_i)) \) has been added, or a new piece. We build by induction on \( k \) a rule \( R_P \) that maps by \( \pi_P \) to \( I \) and such that \( P \) injectively maps to the result of the application of \( R_P \) by \( \pi_P \). □

We conjecture that the previous result actually holds without the pieceful restriction, but its proof would be more intricate. Thanks to this result, we can refine Proposition 6:

Corollary 2. If \( R \) is pieceful and bounded then it is parallelisable by a (finite) subset of \( R^* \).

Proof. Since \( R \) is bounded, the maximum size of a piece is bounded and each piece can be generated by a derivation of length bounded by an integer \( n \), where \( n \) is independent of the instance. □

Since CQ answering with general existential rules is not decidable, \( R^* \) may be infinite. The next example shows that \( R^* \) can be infinite even for \( R \) a bounded set of rules, which may seem surprising.

Example 9. We consider again the prime example, where \( R = \{R_1, R_2\} \) is bounded. Let us build \( R^* \):
\[
R_1 : A(x) \rightarrow \exists z \ p(x, z)
\]
\[
R_2 : p(x, z) \land B(y) \rightarrow r(z, y)
\]
\[
R_2 \circ R_1 : A(x) \land B(y) \rightarrow \exists z \ p(x, z) \land r(z, y)
\]
\[
R_2 \circ (R_2 \circ R_1) : A(x) \land B(y) \land B(y_1) \rightarrow \exists z \ p(x, z) \land r(z, y) \land r(z, y_1)
\]

etc. At each step, one obtains a new rule by the composition \( R_2 \circ R^* \), where \( R^* \) is the rule created at the preceding step:
\[
A(x) \land B(y) \land B(y_1) \ldots B(y_n) \rightarrow \exists z \ p(x, z) \land r(z, y) \land r(z, y_1) \land r(z, y_1) \ldots r(z, y_n)
\]
Not only \( R^* \) is infinite, but no finite subset of it is complete.

Moreover, the previous example shows that rule compositions of the form \( R \circ R^* \), with \( R \in R \) and \( R^* \in R^* \) are required to achieve completeness, while rule compositions of the form \( R^* \circ R \) are sufficient in the datalog fragment.

4.2 Existential Stability

In Sect. 3.3, we have shown that a rule set is parallelisable if and only if it is both bounded and pieceful, with this last notion being defined by the behavior of rules during the chase. The next question we study is whether pieceful rule sets can be characterized by their behavior during rule composition.

We first introduce the ‘existential stability’ property (the reason for this name will be explained in Sect. 4.3).

Definition 7 (Existential stability). Given rules \( R_1 \) and \( R_2 \), we say that a piece-unifier \( \mu = (B'_2, H'_1, u) \) of \( \text{body}(R_2) \) with \( R_1 \) satisfies the (existential) stability property if the following holds:
- either \( u(\text{fr}(R_2)) \cap \text{exist}(R_1) = \emptyset \),
- or \( \text{fr}(R_2) \subseteq \text{var}(B_2) \).

This notion is extended to a rule set: \( R \) satisfies the stability property if, for any rules \( R_1 \) and \( R_2 \) in \( R \), any piece-unifier of \( R_2 \) with \( R_1 \) satisfies the stability property.

Informally, the stability property says that when a frontier variable from \( R_2 \) is unified with an existential variable from \( R_1 \) then all the frontier variables from \( R_2 \) are unified. By the next example, we point out that the stability property of a rule set may not be preserved when composed rules are added.

Example 10. Let \( R \) from Example 8. It can be checked that it has the stability property. Now, consider \( R_2 \circ R_1 \) and \( R_3 : R_2 \circ R_1 : A(x) \rightarrow \exists z \ p(x, z) \land B(z)
\]
\[
R_3 : C(x) \land B(y) \rightarrow r(x, y)
\]
Then, \( R_3 \circ (R_2 \circ R_1) \) involves a piece-unifier that does not satisfy the stability property: \( \text{fr}(R_3) = \{x, y\} \) is unified with \( z \in \text{exist}(R_2 \circ R_1) \) but \( x \) is not unified, hence \( R \cup \{R_2 \circ R_1\} \) does not have the stability property.

We say that a rule set \( R \) is stable at the infinite if \( R^* \) satisfies the stability property. Next, we show that pieceful rule sets are exactly those rule sets stable at the infinite.

Proposition 8. Any pieceful rule set satisfies the stability property.

Proof. Let \( R_1 : B_1 \rightarrow H_1 \) and \( R_2 : B_2 \rightarrow H_2 \) be two rules of a pieceful rule set and let \( \mu = (B'_2, H'_1, u) \) be a piece-unifier of \( \text{body}(R_2) \) with \( R_1 \). Assume that \( \mu \) does not satisfy the stability property. Let \( I = u(B_1) \cup u(B_2 \setminus B'_2) \).

For simplicity here, we confine \( I \) and its freezing, and we assume that safe renumarations are the identity (indeed, we will consider a single application of \( R_1 \) followed by a single application of \( R_2 \). \( R_1 \)) is applicable on \( I \) by a homomorphism \( h_1 \) extending \( u(\text{var}(B_1), i.e., for all \( x \in \text{var}(B_1), h_1(x) = u(x) \) if \( x \in \text{fr}(R_1) \), otherwise \( h_1(x) = x \). \( R_2 \) is applicable on the result of this application, \( \text{fr}(R_2) \cap \text{exist}(R_1) = \emptyset \).

Moreover, the previous example shows that rule compositions of the form \( R \circ R^* \), with \( R \in R \) and \( R^* \in R^* \) are required to achieve completeness, while rule compositions of the form \( R^* \circ R \) are sufficient in the datalog fragment.

Proposition 9. If \( R \) is pieceful, then for any rules \( R_1 \) and \( R_2 \), \( \text{fr}(R_2) \cap \text{exist}(R_1) = \emptyset \).

Proof. (Sketch) We show the contrapositive. Assume \( \text{fr}(R_2) \cap \text{exist}(R_1) \neq \emptyset \). Let \( D' = I_0', \ldots, I_{n+1}' \) be a pieceful \( R \)-derivation on which \( (R_{n+1}, \pi_{n+1}) \) is applicable in a non-pieceful way. We build a non-pieceful \( R \)-derivation \( D = I_0, \ldots, I_{n+1} \) by induction on \( n \), which satisfies the following:
• For all \(1 \leq i \leq n\), there is an isomorphism \(\psi_i\) from \(I'_i\) to \(I_{\varphi(i)}\).

• For any set \(A_j\) (produced by an application in \(D\)), there is \(A'_k\) (produced by an application in \(D'\)) s.t. \(A_j \subseteq \psi_n(A'_k)\).

Consider now \((R_{n+1}, \pi_{n+1})\). Then \(\psi_n \circ \pi_{n+1}\) is a homomorphism from \(\text{body}(R_{n+1})\) to \(I_{\varphi(n)}\). If \(R_{n+1} \in \mathcal{R}\), by hypothesis on \((R_{n+1}, \pi_{n+1})\), there is \(A'_k\) s.t. \(\pi_{n+1}(\text{fr}(R_{n+1})) \subseteq \text{term}(A'_k)\). By induction hypothesis, for every \(A_j\) in \(D\), there is \(A'_k\) s.t. \(A_j \subseteq \psi_n(A'_k)\). Hence, there is no \(A_j\) in \(D\) s.t. \(\pi_{n+1}(\text{fr}(R_{n+1})) \subseteq \text{term}(A'_k)\), and \(R\) is not pieceful. If \(R_{n+1} = R_2 \circ_{\varphi} R_1\), the same reasoning applies, noting that, since \(\varphi\) satisfies the stability property, either \(\text{fr}(R_{n+1}) \subseteq u(\text{fr}(R_2))\) or \(\text{fr}(R_{n+1}) \subseteq u(\text{fr}(R_1))\).

From Prop. 8 and 9, we obtain that pieceful rule sets are stable at the infinite. We now show the converse direction.

**Proposition 10.** Any rule set that is stable at the infinite is pieceful.

**Proof.** (Sketch) We prove the result by contrapositive. Considering the first application \((R, \pi)\) that violates the pieceful constraint in a derivation, we consider a piece \(P\) that contains \(\pi(x)\) for some \(x \in \text{fr}(R)\). We consider \(R_P\) that generates \(P\) (using Proposition 7), and build a piece-unifier \(\mu\) of \(\text{body}(R)\) with \(R_P\) that violates the stability property.

From the three previous propositions, we obtain the desired result:

**Theorem 2.** A rule set is pieceful if and only if it is stable at the infinite.

Finally, as a corollary of Th. 1 and 2, we obtain another characterization of parallelisable sets of rules.

**Corollary 3.** A rule set is parallelisable if and only if it is both bounded and stable at the infinite.

### 4.3 Beyond Existential Composition

In this section, we question the notion of rule composition and provide preliminary findings. We define another rule composition operation, which seems to fit better with our intuition and is more succinct (hence, its name ‘compact’), but which goes beyond existential rules. We then show that, for piece-unifiers that satisfy the stability property, existential and compact compositions actually coincide.

For datalog, we know that \(\mathcal{R}^*\) is finite if and only if \(\mathcal{R}\) is bounded. To better understand why this is no longer true for existential rules, let us focus on compositions of the form \(R_2 \circ R_1\), with \(\text{exist}(R_1) \neq \emptyset\). Intuitively, the rules \(R_2 \circ R_1\) capture the situations in the chase where ‘an application of \(R_1\) leads to a new application of \(R_2\).’ More formally: for any instance \(I\), application of \(R_1\) to \(I\) yielding \(I_1\), homomorphism \(\pi_2\) from \(\text{body}(R_2)\) to \(I_1\) such that \(\pi_2(\text{body}(R_2)) \not\subseteq I_1\), with \(I_2 = \pi(I_1, R_2, \pi_2)\), there is a composed rule \(R_2 \circ R_1\) whose application to \(I\) yields an instance isomorphic to \(I_2\). One might be tempted to conclude that the set of all rules of the form \(R_2 \circ_{\varphi} R_1\) (i.e., for all piece-unifiers \(\mu\)) is able to capture ‘all applications of \(R_2\) that use an atom brought by an application of \(R_1\)’, i.e., \(\text{chase}_1(I, \{R_1, R_2 \circ_{\varphi} R_1 \mid \forall \mu\})\) would be equivalent to \(I = \text{chase}_1(I, \{R_1\}) \cup \{\alpha(I_1, R_2, \pi_2) \mid \pi_2(\text{body}(R_2)) \not\subseteq I\}\).

However, this does not hold, as illustrated below.

**Example 11.** Consider again the prime example with \(\mathcal{R} = \{R_1, R_2\}:\)

\[
R_1 : A(x) \rightarrow \exists z \, p(x, z) \\
R_2 : p(x, z) \land B(y) \rightarrow r(z, y) \\
R_2 \circ R_1 : A(x) \land B(y) \rightarrow \exists z \, p(x, z) \land r(z, y).
\]

Let \(I = \{A(a), B(b), B(c)\}\). Then:

\[
\text{chase}_1(I, \mathcal{R}) = I \cup \{p(a, z_0), r(z_0, b), r(z_0, c)\}
\]

As it is obtained by one application of \(R_1\) which triggers two parallel applications of \(R_2\), this also corresponds to the above \((I_1 = \text{chase}_1(I, \{R_1\}) \cup \{\alpha(I_1, R_2, \pi_2) \mid \pi_2(\text{body}(R_2)) \not\subseteq I\})\). One (breadth-first) chase step with \(\mathcal{R} \cup \{R_2 \circ R_1\}\) would produce instead:

\[
I \cup \{p(a, z_0), p(a, z_1), r(z_1, b), p(a, z_2), r(z_2, c)\}
\]

Note that this is here equal to \(\text{chase}_1(I, \{R_1, R_2 \circ_{\varphi} R_1 \mid \forall \mu\})\). We can see that two nulls \(z_1\) and \(z_2\) are created instead of a single one. Obviously, both results are not equivalent. E.g., the Boolean CQ \(q = \exists u \, r(u, b) \land r(u, c)\) would be answered positively in the first case, but not in the second.

In the previous example, the logical formula associated with \(R_2 \circ R_1\) is the following:

\[
\forall x \forall y (A(x) \land B(y) \rightarrow \exists z \, (p(x, z) \land r(z, y))).
\]

Instead, we propose to interpret rule composition as:

\[
\forall x (A(x) \rightarrow \exists z \, p(x, z) \land \forall y (B(y) \rightarrow r(z, y)))
\]

By removing the knowledge entailed by \(R_1\), we obtain:

\[
R_2 \circ R_1 = \forall x \exists z \forall y (A(x) \land B(y) \rightarrow p(x, z) \land r(z, y)).
\]

**Definition 8 (Compact Composition).** Let \(R_1 = \forall x_1 \forall y_1 \mid B_1(x_1, y_1) \rightarrow \exists z_1 \, H_1(x_1, z_1)\) and \(R_2 = \forall x_2 \forall y_2 \mid B_2(x_2, y_2) \rightarrow \exists z_2 \, H_2(x_2, z_2)\) .

Let \(\mu = (B_2', H_2', u)\) be a piece-unifier of \(B_2\) with \(R_1\).

The compact composition of \(R_2\) with \(R_1\) w.r.t. \(\mu\), denoted by \(R_2 \bullet_{\mu} R_1\) is the following closed formula:

\[
\forall x_1' \forall y_1' \exists z_1 \forall x_2' \forall y_2' (u(B_1(x_1')) \land u(B_2 \setminus B_2') \rightarrow \exists z_2' \, (u(H_1(x_1') \land u(H_2(x_2'))) \land \forall y_2' (u(B_2', y_2') \setminus \text{var}(B_2'))
\]

Compact composition is more succinct than existential composition, since a single \(\bullet\)-composed rule may capture an unbounded number of \(\circ\)-composed rules. However, the resulting formula is generally not an existential rule. We show below that, when the piece-unifiers involved in rule composition satisfy the stability property, the result of compact composition is equivalent to an existential rule (hence the name ‘existential stability’) and it coincides with existential composition (for clarity, we consider below the general form of existential composition, i.e., ignore Point 1 in Def. 5).
Proposition 11. When the stability property is satisfied, the compact composition is equivalent to the existential composition, i.e., for all rules $R_1$ and $R_2$, and any piece-unifier $\mu$ of body$(R_2)$ with $R_1$ satisfying the stability property, $R_2 \circ_\mu R_1 \equiv R_2 \bullet R_1$ (where $\equiv$ denotes the logical equivalence and $\circ$ is defined according to Point 2 of Def. 5).

Proof. Note that $R_2 \circ_\mu R_1$ is equivalent to the formula obtained from $R_2 \bullet \mu R_1$ by moving $\exists z_1$ after $\forall x_2 \forall y_2$. Here, such an inversion of quantifiers can be done without change of semantics if we can group the atoms in $R_2 \bullet \mu R_1$ into two sets, such that one contains all the atoms with variables in $z_1$ and the other all the atoms with variables in $x'_2 \cup y'_2$. Since $u(H_2)$ may contain variables from both $x'_2$ and $z_1$, this is possible if and only if $u(H_2)$ contains no variable from $x'_2$ or no variable from $z_1$. We check that it is indeed the case when $\mu$ has the stability property: if $u(fr(R_2)) \cap \text{exist}(R_1) = \emptyset$, then $u(H_2)$ does not contain any variable from $z_1$; if $fr(R_2) \subseteq \text{var}(B_2)$, then $x'_2$ is empty, hence $u(H_2)$ does not contain any variable from $x'_2$. □

Finally, one could think of skolemizing existential rules to get (specific) logic-programming rules. Briefly, skolemization consists of replacing each existential variable in a rule head by a fresh functional term over the rule frontier. Then, rule composition is based on classical (most general) unifiers. However, as illustrated below, the composition of two skolemized existential rules may not be a skolemized existential rule. Actually, such composition can be seen as the skolemization of the formula obtained by compact composition, which leads us again beyond the existential rule fragment.

Example 12 (Skolem composition). Consider the skolemization (noted sk) of the rules from the prime example:

$\text{sk}(R_1) : A(x) \rightarrow p(x, f(x))$

$\text{sk}(R_2) : R_2 : p(x, z) \land B(y) \rightarrow r(z, y)$

Then, the composition of $\text{sk}(R_2)$ with $\text{sk}(R_1)$ yields the following rule, where $p(x, f(x))$ could be removed:

$A(x) \land B(y) \rightarrow p(x, f(x)) \land r(f(x), y)$

This rule is not the skolemization of any existential rule because $f$ does not span over the whole rule frontier $\{x, y\}$. Instead, it is $\text{sk}(R_2 \bullet R_1)$.

5 Concluding Remarks

In this paper, we introduce the notion of parallelisability of a set of existential rules and characterize parallelisable rule sets in two different ways. One characterization relies on the behavior of rules during the chase, which leads to define a new class of existential rules, namely pieceful. Another characterization relies on the behavior of rules during rewriting, which led us to question the notion of rule composition. We believe that these results open up many perspectives, which we now outline.

Application to OBDA Mature systems, such as OnTop (Calvanese et al. 2017) or Mastro (Calvanese et al. 2011), are based on lightweight description logics (typically DL-Lite$\mathcal{R}$ underpinning the W3C language OWL2 QL) and the mapping is GAV (i.e., mapping assertions $q_S(x) \rightarrow q_O(x)$ satisfy $\text{var}(q_O) \subseteq x$). Some other OBDA systems are based on the lightweight ontological language RDFS, e.g., UltraWrap (Sequeda, Arenas, and Miranker 2014), where RDFS is extended with inverse and transitive properties, and mappings are still GAV, and Obi-Wan (Buron et al. 2020a), strictly restricted to RDFS but with GLAV mappings (i.e., $q_O$ is any CQ). We believe that the existential rule framework is particularly well suited to the development of OBDA systems in more expressive settings. Indeed, existential rules are able to express both ontological knowledge and relational GLAV mappings; GLAV mappings provide increased flexibility compared to GAV mappings, by their ability to invent values, thanks to existential variables. This yields a uniform setting for the whole OBDA specification, thereby facilitating the analysis of the interactions between $\mathcal{C}$ and $\mathcal{M}$, which is key to efficiency. Furthermore, a rich family of existential rule dialects achieving various expressivity/tractability tradeoffs are available. In this paper, we have taken a first step towards the design of compilation techniques for this setting, by characterizing the notion of parallelisability. Indeed, when the rule set is parallelisable, ontological reasoning can be totally compiled into the mapping. Our results pave the way for the development of query answering techniques exploiting parallelisation and the specificities of existential rule dialects. Another interesting extension of our work would be to investigate combined reasoning (Lutz, Toman, and Wolter 2009) or partitioned reasoning (Baget et al. 2011a), which would allow us to go beyond parallelisable rule sets.

Deepening Theoretical Foundations The novel pieceful class is of interest in itself, specially in the context of query answering. It includes both datalog and frontier-guarded, a prominent class of existential rules. Frontier-guarded itself covers some major DL dialects used in query answering (e.g., DL-Lite$\mathcal{R}$ or $\mathcal{ELHI}$, see (Mugnier 2020) for more details on the relationships between these DLs and the ghts family). We conjecture that CQ answering with pieceful rules is in PTime for data complexity. By all these features, the pieceful class is related to the recently introduced warded class (Bellomarini, Sallinger, and Gottlob 2018), even if both are incomparable, at least from a syntactic viewpoint (our prime example is warded but not pieceful, on the other hand warded does not include frontier-guarded).

Concerning the notion of parallelisability itself, we based our study on the semi-oblivious chase. In line with this, parallelisability requires an injective homomorphism from $\text{chase}_\infty(I, R)$ to $\text{chase}_1(I, R')$, where $R'$ is the parallelisation of $R$. Dropping the injectivity requirement, i.e., considering logical equivalence, would lead to a more general notion of parallelisability, which remains to be investigated.

Finally, we have seen that compact rule composition leads us beyond the existential rule fragment. The obtained formulas belong to strictly more expressive logical fragments that have been studied in particular in (Gottlob, Pichler, and Sallinger 2015). Whether such fragments could lead to parallelisation techniques is another open issue.
