Abstract

Spelling normalisation is a useful step in the study and analysis of historical language texts, whether it is manual analysis by experts or automatic analysis using downstream natural language processing (NLP) tools. Not only does it help to homogenise the variable spelling that often exists in historical texts, but it also facilitates the use of off-the-shelf contemporary NLP tools, if contemporary spelling conventions are used for normalisation. We present *FREEMnorm*, a new benchmark for the normalisation of Early Modern French (from the 17th century) into contemporary French and provide a thorough comparison of three different normalisation methods: ABA, an alignment-based approach and MT-approaches, (both statistical and neural), including extensive parameter searching, which is often missing in the normalisation literature.

Keywords: Digital Humanities, Normalisation, Spelling, Modern French, Machine Translation, Historical

1. Introduction

Computational approaches have recently been playing an increasing role in the humanities (Gabay, 2021), especially concerning the study of textual documents. Historical documents are particularly interesting, as they are an invaluable source of historical information and are crucial witnesses of language evolution.

Whether documents are to be studied manually by philologists and literary experts or analysed automatically using downstream natural language processing (NLP) tasks such as part-of-speech (PoS) tagging and parsing, a useful preliminary step is *normalisation*, which consists in modernising the spelling of the documents to conform to contemporary spelling conventions. Normalisation has the effect of (i) reducing spelling variation generally present in historical documents, often written at a time spelling was not standardised, and (ii) reducing the gap between the historic state of the language and the contemporary state. Importantly, this allows us to apply off-the-shelf NLP tools to old texts and limit the performance drop that can usually be expected, for example for tagging and parsing (Pettersson et al., 2013b) or geographical named entity recognition (Kogkitsidou and Gambette, 2020).

There has been a considerable amount of previous research in historical spelling normalisation, with a range of methods being developed, including manually developed rules (Porta et al., 2013; Riguet, 2019; Baron and Rayson, 2009), those exploiting edit distances and other external resources such as lexicons (Mitankin et al., 2014) and machine translation (MT) approaches, both statistical (Scherrer and Erjavec, 2013; Domingo and Casacuberta, 2018a) and neural (Bollmann and Søgaard, 2016; Härmäläinen et al., 2018). Despite this, questions still remain regarding which method is the most effective, particularly between statistical MT (SMT) and neural MT (NMT) approaches. There has

for example been little research in optimising these models for the particular task, which could lead to false conclusions being drawn about which model is best; as has been previously shown for low-resource tasks, neural models in particular are sensitive to model size, training parameters and the degree of subword segmentation applied to texts (Sennrich and Zhang, 2019; Fourrier et al., 2021).

Our focus in this paper is on the normalisation into contemporary French of Early Modern French (also known as Modern French or Classical French), which is French from the 17th century. Despite several recent efforts (Riguet, 2019; Gabay and Barrault, 2020; Gabay et al., 2019), there has so far been very little research has been carried out on spelling normalisation for historical French, and so we aim to fill in this gap. Figure 1 illustrates a few of the normalisation types observed, from simple typographic changes (e.g. *l* → *s*), changes to segmentation (*long temps* ‘a long time’ → *longtemps*), changes reflecting language change (*efloit* ‘(s/he) was’ → *était*) and the use of classical false etymological spellings (e.g. *ç* being used in Modern French *ſçavoir* ‘to know’ as a link to Latin *scire*, from which it does not originate).

In this paper, we present the parallel normalisation corpus, *FREEMnorm* (for Early Modern French), on which we train and evaluate, and, in addition to baseline models, we compare three methods: (i) an alignment-based approach, called ABA, using automatically learned word correspondences from a parallel corpus, (ii) phrase-based SMT, and (iii) NMT, comparing an LSTM model (Bahdanau et al., 2015) and a transformer (Vaswani et al., 2017). We find that despite extensive parameter optimisation for NMT models, SMT produces the best results overall, with all methods largely exceeding the baselines. Our comparison shows that the methods exhibit quite different be-

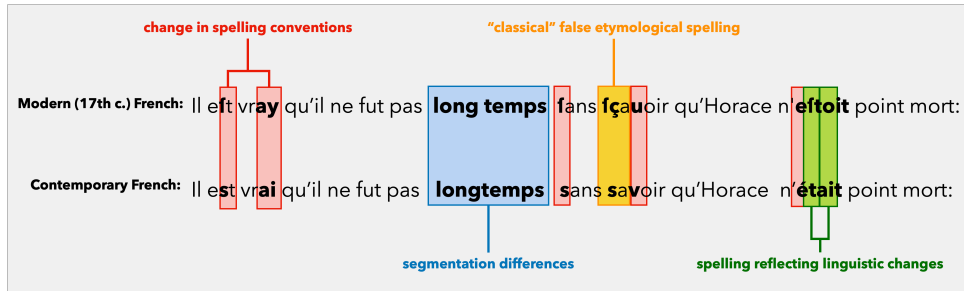

Figure 1: A Modern French sentence and its contemporary French normalisation.

haviour in terms of how conservative or inventive they are, which could be useful information depending on the downstream task (e.g. as a pre-annotation tool for manual annotation or a downstream NLP application). Our main contributions can be summarised as follows:

- Introduction of a new benchmark of the normalisation of Modern French, which can be used in further research.
- Extensive experiments comparing an alignment-based approach (ABA) with three MT approaches (SMT, LSTM and Transformer), with best results achieved by SMT. We also show that a lexicon-based post-processing step can systematically improve over all other methods tested.
- We freely distribute the data,¹ scripts and state-of-the-art normalisation models² for Modern French.

2. Related work

A considerable amount of work has been carried out in historical spelling normalisation, across various languages, with research dating back to the 1980s (Fix, 1980). A range of different approaches have been developed in that time, including rule-based approaches (Porta et al., 2013; Riguët, 2019), the use of various types of edit-distance (Hauser and Schulz, 2007; Bollmann, 2012; Pettersson et al., 2013a) and MT-style approaches, both statistical (Vilar et al., 2007; Scherrer and Erjavec, 2013; Ljubesic et al., 2016; Domingo et al., 2017) and neural (Korchagina, 2017; Domingo and Casacuberta, 2018b; Tang et al., 2018). Interestingly, all of these approaches remain useful today, thanks to the fact that they have different strengths, depending on the type of normalisation and the amount of data available (Bollmann, 2019).

2.1. Word lists, rules and edit-based approaches

Approaches relying on word lists, consisting in simply replacing historical variants by their normalised equivalent have been developed in several languages: English, German, Portuguese (Piotrowski, 2012) and Slovene (Erjavec et al., 2011).

Many rule-based and edit-distance-based approaches are unsupervised (i.e. they do not require parallel data), which is a considerable advantage, especially for historical varieties for which annotated data is not readily available. Rules can be developed manually by experts (Porta et al., 2013; Riguët, 2019; Baron and Rayson, 2009) or be extracted from a comparison of historical and modern word lists or parallel data if this is available (Bollmann et al., 2011).

The use of edit distance, using for example Levenshtein distance is often a strong baseline (Pettersson et al., 2013a), due to the fact that the surface forms of historical and contemporary spellings are often very similar and the alignment between both words and characters in the two varieties is almost perfectly monotonic. Basic edit-distance can be enhanced with specific weights, for different edits (Bollmann et al., 2011) or based on characters or character groups (Hauser and Schulz, 2007; Bollmann, 2012), given the observation that certain errors are more serious than others.

2.2. Normalisation as MT

MT approaches to the problem have been popular, with the historical and modern states of the language being treated as the source and target languages respectively.

Characters, subword or words? Most previous research has focused on character-based MT, which models transformations at the level of individual characters (Vilar et al., 2007; Scherrer and Erjavec, 2013; Pettersson et al., 2013b; Domingo and Casacuberta, 2021), which makes sense for the task of spelling normalisation, as it often involves local transformations and largely monotonic alignments between source and target sentences. However, there has since been work exploring word translation, subword translation (Tang et al., 2018) or a mixture of these (Vilar et al., 2007; Domingo and Casacuberta, 2021). It is rare however for works in historical spelling normalisation to explore the optimal degree of segmentation, although Tang et al. (2018) do find subwords to be more effective than character-based: character-based segmentation offers a greater possibility for generalisation with the caveat that it requires the model to learn to translate longer sequences and learn patterns better, whereas word or subword segmentation can exploit models' ability to

¹<https://doi.org/10.5281/zenodo.5865428>

²<https://github.com/rbawden/ModFr-Norm>

memorise better, but may run the risk of limited generalisation, especially to unseen or less frequent words.

SMT or NMT? The first approaches were with SMT (Koehn et al., 2007), which proved more effective than rule-based and edit-distance based approaches (Petersson et al., 2014; Hämäläinen et al., 2018; Bollmann, 2019), when there is parallel data available, and even when this data is produced synthetically (Scherrer and Erjavec, 2013; Domingo and Casacuberta, 2018a). NMT approaches to historical spelling normalisation were developed as it took off in the domain of general MT (Bollmann and Sjøgaard, 2016; Hämäläinen et al., 2018). Comparisons between SMT and NMT show different results, with SMT being superior in some cases (Domingo and Casacuberta, 2018a), and NMT in others (Bollmann, 2019), provided enough parallel data is available (Bollmann, 2019). Importantly, the methods appear to have different behaviours and therefore their own strengths and weaknesses, meaning that a single method (including rule-based approaches) is not necessarily a systematically better choice (Hämäläinen et al., 2018; Robertson and Goldwater, 2018).

Word translation vs. sentence translation A considerable portion of the research in historical normalisation is based on the normalisation of word lists, so of words in isolation. However, as discussed in (Ljubescic et al., 2016), it can be beneficial in some contexts to normalise whole sentences (where there is ambiguity in the normalised form that should be chosen). This has the disadvantage of creating longer sequences to process, but is necessary in order to hope to handle all phenomena. The development of parallel corpora rather than word lists has encouraged research in this direction (Tjong Kim Sang et al., 2017; Gabay and Barrault, 2020) (Ortiz Suarez et al., 2022).

2.3. Normalisation for historical French

Despite there being a plethora of research on historical spelling normalisation, little research has been done so far on historical French, with most work focusing on Dutch, German, Hungarian, Slovene, and Swedish, helped by the existence of benchmark data (Dipper and Schultz-Balluff, 2013) and shared tasks (Ljubescic et al., 2016; Tjong Kim Sang et al., 2017).

A collaborative word list associating normalised versions of historical words in French was started in 2009 on the Wikisource digital library³, which is available for automatic normalisation through word substitution (The French Wikisource Community, 2022). Recently, there has been some preliminary research, with the development of a parallel corpus for the normalisation of Modern French (from the 17th c.) (Ortiz Suarez et al., 2022) and first baselines, including rule-based (Riguet, 2019) and NMT-style approaches (Gabay et al., 2019; Gabay and Barrault, 2020). Gabay and Barrault (2020) compare character-based SMT and NMT

at different granularities (words, subwords and characters): NMT outperformed SMT, and for NMT, the best input representations were found to be words, then characters, then subwords. However, they do not seem to perform a comparison of different levels of subword segmentation or of different sizes of architecture, which has been shown to be important when drawing conclusions about the usability of NMT in low-resource settings (Sennrich and Zhang, 2019).

3. Approaches Compared

We present and compare several approaches, representing a wide range of techniques: (i) an alignment-based method using a parallel corpus (Section 3.1), (ii) statistical MT (Section 3.2.1), (iii) neural MT, testing both LSTM and transformer models (Section 3.2.2). In addition to comparing these approaches to two baselines described in Section 6.1, we also assess the impact of a lexicon-based post-processing described in Section 3.3.

3.1. ABA: alignment-based

The ABA method (short for alignment-based method), is a hybrid approach consisting of (i) word-level transformation rules that are automatically learned from an aligned corpus and (ii) character-level transformation rules, which were manually designed by observing frequent character transformations in the aligned corpus.

The ABA normalisation method, which has similarities with the approach of VARD2 developed for the English language (Baron and Rayson, 2009), works as follows.

Creation of a word substitution lexicon The first step is to learn a word replacement lexicon using a parallel training set. This is done using the classical dynamic programming Needleman-Wunsch alignment algorithm (Needleman and Wunsch, 1970) to optimally align tokenised parallel sentences at token level, adding a score of 4 for matching words in lowercase (or for *et* and *&* ‘and’ which are considered equivalent) and a penalty of -1 for word insertion, deletion or mismatch if the non-matching words have a Levenshtein distance at least 4 or at least the length of each word. For mismatches between words at Levenshtein distance $d < 4$ and strictly smaller than the length of both words, $4 - d$ is the mismatch score taken into account by the alignment algorithm. Notice that the Levenshtein distance is computed with a penalty of 1 for insertion or deletion and 2 for character mismatch. These scores were adjusted experimentally after considering the alignment results on some training corpus.

Substitution step The second step uses this replacement lexicon as well as a contemporary French lexicon built by combining Morphalou 3.1 (ATILF, 2019) with lexicons of proper nouns developed for CasEN 1.4 (Maurel et al., 2011): `CasEN.Dico.dic`, `Prolex-Unitex-BestOf_2_2_fra.dic` (CasEN Team, 2019) and `Prolex-Unitex_1.2.dic` (Prolex Team, 2013). It proceeds in the following way.

³On January 17th, 2022, the whole list contains 15,470 words and expressions and their normalised equivalents.

After simple tokenisation⁴ of the input text, for each token: 1) if it is present in the contemporary French lexicon, it is kept as it is; 2) otherwise, if it is present in the word replacement lexicon, it is replaced by the associated normalised version in this lexicon; 3) otherwise, it is transformed by a combination of character replacement rules detailed in Appendix A, designed after careful analysis of the aligned words in the training corpus and available in the `apply_rules` function of the `modern.py` script in ABA’s distribution;⁵ among the obtained candidate tokens, the first one found in the contemporary French lexicon is selected; 4) otherwise, if no candidate generated by character transformation rules is selected, then the original token is kept.

3.2. MT: SMT and NMT

Following promising results for other languages (Scherrer and Erjavec, 2013; Tang et al., 2018) and modern French (Gabay et al., 2019; Gabay and Barrault, 2020), we provide a comparison of phrase-based statistical MT and neural MT.

3.2.1. Phrase-based SMT

The aim of SMT is to automatically find the most probable translation \hat{t} given a source sentence s such that $\hat{t} = \operatorname{argmax}_{t \in T} P(s|t)P(t)$, where $P(s|t)$ models the adequacy of translation, and $P(t)$ the target language model probability, which can be seen as a measure of the fluency/grammatical of the prediction. The state of the art in SMT is phrase-based MT, where a prediction’s score is the sum of scores from various scoring components, including a phrase table (for the translation probability), a language model (for the language model probability), a reordering (or distortion) model and a length penalty. The main implementation used for phrase-based SMT is the Moses toolkit (Koehn et al., 2007), which we use here in this paper.

Phrase-based SMT was the state of the art in MT until around 2015, when NMT first outperformed it (Bahdanau et al., 2015). The main disadvantages of SMT with respect to NMT is the limited ability to model longer distant dependencies and to model semantic relationships between input units, given that probabilities are calculated based on discrete surface forms rather than continuous representations. It nevertheless remains relevant in certain settings, notably when little parallel training data is available (Trieu et al., 2017; Fourier et al., 2021). For historical spelling normalisation, some works have shown that it can outperform neural approaches, particular in these lower-resource settings (Domingo and Casacuberta, 2018a).

3.2.2. NMT (LSTM and TRANSFORMER)

NMT uses neural networks to find the most probable translation. The standard architecture is an encoder-decoder with an attention mechanism (Bahdanau et al.,

2015). The role of the encoder is to encode the source sequence and the decoder to sequentially produce the target sequence, given the previously translated words and a representation of the input sequence specific to that decoding step (calculated using attention). Importantly, these models work with continuous representations of words, allowing for a greater capacity to generalise across forms and an improved handling of complex linguistic phenomena. The first such models were based on recurrent neural networks (using recurrent units such as LSTM for example), involving sequentially encoding the input and sequentially decoding the output. The current state of the art are transformers, which involve replacing recurrence with self-attention (Vaswani et al., 2017). Transformers have the advantage of speed in training and tend also to perform better, although this does not always hold for low-resource settings (Fourier et al., 2021).

NMT model performance is sensitive to the size of the architecture, subword segmentation and training parameters. Sennrich and Zhang (2019) show that previous conclusions about the superiority of SMT systems over NMT in low-resource scenarios do not necessarily hold as long as the NMT parameters are well chosen, highlighting the need to perform adequate parameter search before drawing conclusions. In line with this, we perform extensive hyper-parameter searches of both LSTM and transformer models (Section 6.3).

3.3. Optional Lefff-based post-processing

All three approaches described above rely on parallel training data. Despite the generalisation capabilities of such models, it might be the case that rare situations are not properly dealt with. On the other hand, large-scale lexicons of contemporary French, such as the *Lefff* (Sagot, 2010), can provide high coverage lexical information regarding the target language of the normalisation process.

Based on this observation, we developed a lexicon-based post-processing tool that can be used after any normalisation model and is based on the *Lefff* (version 3.4). It relies on the idea that a normalised text should mostly contain words known to a large-scale contemporary French lexicon. Any token (whitespace- and/or punctuation-separated character sequence) that does not begin with a capital letter (to avoid proper nouns) and that is unknown to the lexicon is eligible for further normalisation. For every such token, we compute a list of possible normalisations based on a small list of permitted transformations.⁶ We then look up all normalisation candidates in our lexicon. If exactly one of the normalisation candidates is known to our lexicon, we replace the input token with this candidate. In all other cases, we leave the token unchanged.

⁴Splitting the sentence on whitespace, the characters . , ! ? ; : and both kinds of apostrophe.

⁵<https://github.com/johnseazer/aba>

⁶The rules: $Vs \rightarrow \hat{V}$ where V is any vowel, $es \rightarrow \acute{e}$, add each possible diacritic to each non-diacritised letter that can have a diacritic (e.g. $u \rightarrow \acute{u}$), $v \rightarrow u$ when preceded by a vowel, $u \rightarrow v$ when preceded by a consonant, $i \rightarrow y$.

4. Evaluating Normalisation

In terms of automatic metrics, the most commonly used are translation edit rate (TER), word accuracy (based on the gold normalised tokens, non-symmetrised) and some works have used traditional metrics for MT (BLEU (Papineni et al., 2002) and CHRF (Popović, 2015)) (Gabay and Barrault, 2020). Arguably the most interpretable metric is word accuracy, since it gives an idea about the number of lexical units that would have to be corrected, whereas MT metrics are less interpretable, given that they are designed to incorporate a certain degree of flexibility concerning word order, which is not relevant for the task of spelling normalisation. On the other hand, they have the advantage of being able to penalise predictions that contain additional (hallucinated) tokens as well as correct tokens, a situation that is plausible given the use of MT models on the sentence level.

We therefore choose to use a symmetrised version of word accuracy, which involves calculating the average between traditional word accuracy (aligning each gold token to a predicted one) but also the reverse calculation (aligning each predicted token to a gold one).⁷ We also evaluate using MT metrics to test how they correlate with word accuracy.

5. Data

For training, development and test data, we present the FREEM corpus (short for *FRENch Early Modern*) called FREEMnorm.⁸ The data covers a range of different genres of text throughout different decades of the 17th century, written in prose or verse, which have been semi-automatically normalised (Gabay et al., 2019) and manually corrected. Most of these texts belong to the *belles-lettres* (literature in its broadest sense), which is the type of source we want to normalise, but additional texts from different traditions (science, law, etc.) are present in the corpus. Some of the transcriptions have been produced specifically for this corpus and others have been borrowed from other projects: transcription rules are therefore not strictly equivalent from one text to another regarding, for instance old characters (e.g. *l*) or abbreviations (e.g. *ō*→*on*). “Normalisation” is understood here as a partial alignment with contemporary French: in some specific cases, specific spelling are maintained to keep the meter of the verse intact (e.g. the adverbial -s: *jusques*+vowel→*jusques* and not *jusqu’* to maintain the three syllables). The dataset has been split into train, dev and test sets, for which basic statistics can be found in Table 1. The split was done such that the test set contains a variety of different genres and periods (see Tables 7) and 5 in

⁷We perform alignment first on the character level using Levenshtein distance and then realign on the token level with respect to the tokenisation of the gold and predicted sequences respectively.

⁸<https://doi.org/10.5281/zenodo.5865428>

the Appendix), some of which are covered in the train and dev set and some of which are unseen.

In terms of the difficulty of the task, although many words remain unchanged between the original Modern French and their contemporary French normalisations (75.7% of all words in the training set), there is a non-negligible number of tricky cases, where normalisation is non-trivial. There are a large number of out-of-vocabulary (OOV) items in both the dev and test sets with respect to the training set, and approximately 0.3% of tokens are ambiguous (i.e. they correspond to several possible normalisations depending on the context). Aside minor differences such as punctuation (which is nevertheless not arbitrary, since it can be determined by context), capitals and accents, there are some interesting cases, such as ambiguity concerning verbal conjugations, which may require more contextual information (See Table 2 for two examples). For these cases, it is necessary to normalise words whilst taking into account their context (as in traditional MT). This justifies processing whole sentences rather than isolated words.

6. Experiments

6.1. Baselines

We compare the approaches described in Section 3 with two baseline approaches, the identity function and a basic rule-based approach.

Identity function This keeps the text unchanged.

Rule-based This is a stronger baseline comprising several dozen regular expressions, which were manually written based on simple corpus statistics from our training set. They range from purely typographic rules, which reflect the evolution of the writing system, to lexical rules, which reflect the evolution of the language. Here are a few examples, ordered from purely typographic to fully lexical:

- $f \rightarrow s$, $\bar{o} \rightarrow om$ if followed by m , b or p , or on otherwise;
- $i \rightarrow j$ at the beginning of a word when followed by a vowel other than i ;
- $estoit \rightarrow \acute{e}tait$ and $estoint \rightarrow \acute{etaient}$.

In addition, we also assess the impact of the lexicon-based post-processing step on these baselines.

6.2. Experimental setup

All NMT models are trained using Fairseq (Ott et al., 2019), with default parameters unless otherwise specified. All models are trained until convergence; the best checkpoint is chosen based on symmetrised word accuracy. Subword segmentation is applied using SENTENCEPIECE (Kudo and Richardson, 2018) and the BPE strategy (Sennrich et al., 2016).

We train SMT models using Moses (Koehn et al., 2007), language models using KenLM (Heafield, 2011). We tune using *kbmira* to maximise BLEU.

Set	#sentences.	#tokens		#unique tokens		#OOV	
		ModFr	Fr	ModFr	Fr	ModFr	Fr
Train	17,930	264,311	263,669	21,329	17,238	-	-
Dev	2,443	40,435	40,294	6,736	5,993	1,766	1,312
Test	5,706	86,432	86,211	10,457	8,915	3,596	2,530

Table 1: Statistics for the FREEMnorm corpus for Modern French (ModFr) and contemporary French (Fr). Texts are tokenised using the Moses tokeniser (Koehn et al., 2007) to calculate statistics and #OOV corresponds to the number of unique out-of-vocabulary tokens.

	Normalisation example 1	Normalisation example 2
nostre ‘our’	quel malheur est le nôtre ‘what woe is ours ’	Les larmes sont trop peu pour pleurer notre mal ‘The tears are too few to cry (for) our pain’
appelez ‘call’	N’ appelez point des yeux le Galant à votre aide ‘Do not call the Galant for help with your eyes’	...Royaumes, par nous vulgairement appelés Siam ‘...kingdoms, known popularly by us as Siam’

Table 2: Two examples of context-dependent ambiguity (Modern French words *nostre* and *appelez*) when normalising to contemporary French.

6.3. Best Model Search

6.3.1. Neural models

For LSTM and Transformer models, we performed hyper-parameter searches to maximise the micro-averaged word symmetrised accuracy on the development set. We explored (i) the network size (cf. Table 3 for LSTM models and Table 4 for Transformer models), (ii) the degree of subword segmentation via different BPE vocabulary sizes (500 1k, 2k, 4k, 8k, 16k, 24k), (iii) the learning rate (0.0005, 0.001, 0.001) and (iv) the batch size (1000, 2000, 3000, 4000 tokens). In order to avoid having to explore the combination of all parameters, we explore hyper-parameters in a step-wise fashion from (i) to (iv), keeping the best parameters from the previous step. We then explore variations on the network size parameters, varying attributes one below and one above the default values. Results are calculated as an average of three differently seed runs for each combination. We begin with default values for all hyper-parameters and varied only those mentioned. Both models performed best with a BPE vocabulary of 1k, batch size of 3000 and learning rate of 0.001. The best network sizes were M for the LSTM, and a variant of the M model for the Transformer, with only 2 encoder layers rather than 4.

6.3.2. Statistical MT model

As for the neural models, we test several different granularities of segmentation: character-based, 500, 1k and 2k.⁹ We use a 4-gram language model trained on the target side of either the parallel training data or the normalised texts of the FREEM max corpus (Gabay et al., 2022). The best subword segmentation is with vocabulary size 500 (interestingly not character-based as what has previously been used) and with the language model trained on the target side of the parallel training data.

⁹Larger vocabulary sizes result in worse scores and were also more difficult to train because of memory problems.

Size	#enc. layers	#dec. layers	embed. dim.
XS	1	1	128
S	2	2	256
M	3	3	384
L	4	4	512

Table 3: Network sizes explored for LSTM models.

Size	#attn. heads	#layers		Dim.	
		enc.	dec.	embed.	ffwd.
S	2	2	2	128	512
M	4	4	4	256	1024
L	8	6	6	512	2048

Table 4: Network sizes explored for Transformer models. L corresponds to Transformer-base.

7. Results

We compare the approaches described in Section 3 according to the three evaluation metrics discussed in Section 4: symmetrised word accuracy (written WordAcc), BLEU and ChrF.

Results are shown in Table 5. For MT approaches, we run each model three times with three random seeds and report the average score and standard deviation. Models (1)-(4) are baselines and already achieve relatively high scores. This is unsurprising, given the large number of words that do not need modifying: the identity function (copying the source text) gives 72.40% word accuracy. The rule-based approach is significantly better than the first baseline, and adding the post-processing step (+Lefff) considerably improves both results. The two statistical approaches, the hybrid ABA and SMT, both perform better than the baselines, with SMT actually performing the best out of all approaches. The NMT models perform slightly worse according to all metrics than SMT. Although the scores

Model	WordAcc (%)	BLEU	ChrF	OOV WordAcc (%)
<i>Baseline models</i>				
(1) Identity	72.40	40.25	73.77	41.89
(2) Identify + Lefff	85.80	66.78	87.40	63.08

Table 5: Results on the test set. “+ Lefff” indicates that the lexicon-based post-processing was applied.

of LSTM and TRANSFORMER are incredible similar, LSTM scores are slightly higher. It is an interesting find that the SMT outperforms NMT in our scenario, as this goes against recent findings for Modern French (Gabay and Barrault, 2020), despite us having more parallel data available. As for the baselines, adding the post-processing step improves both statistical and neural models, with the best result being SMT+Lefff with a symmetrised word accuracy of 97%.

As recommended by Robertson and Goldwater (2018), we also calculate word accuracy for OOV tokens only (based on the gold normalisation). Results (Table 6) show that the highest scoring model for OOV accuracy for a single model is LSTM, although if post-processing is applied, both SMT and LSTM show similar scores (bearing in mind the variance in scores). Adding the post-processing step significantly helps the OOV accuracy of all methods, showing that it is an important complementary step.

The three evaluation metrics reveal the same pattern in results for these models, with BLEU varying more in absolute scores than the other metrics.

8. Comparative Analysis

8.1. How Similar are the Methods?

In Table 2, we compare the predictions token by token and report the percentage of identical normalisations between methods.¹⁰ Unsurprisingly, the neural methods (LSTM and transformer) are most similar to each other, with SMT being most similar to the Transformer.

8.2. Conservative or Zealous?

Depending on how the tool is to be applied, it can be better to have a more conservative or zealous model.

¹⁰The analysis is computed against the first prediction for methods for which three random seeds were used.

Table 6: Word accuracy on OOV target tokens (%)

	Rule-based	ABA	SMT	LSTM	Transformer
Rule-based	100.00	91.64	89.95	89.77	89.22
ABA	91.64	100.00	95.95	95.41	94.81
SMT	89.95	95.95	100.00	97.19	96.84
LSTM	89.77	95.41	97.19	100.00	97.68
Transformer	89.22	94.81	96.84	97.68	100.00

Figure 2: The percentage of identically normalised test set tokens between methods.

If automatic normalisation is to be used as a pre-annotation tool to help experts manually normalise texts, it is important that the automatic step does not introduce too many serious errors that could be more difficult to detect and time-consuming to correct. This is a concern notably for NMT-based models (Gabay and Barrault, 2020), which can be more creative in their transformation than either rule-based or SMT-based approaches. It may however be less of a problem if automatic normalisation is to be used for certain downstream tasks using standard contemporary NLP tools (e.g. PoS-tagging or parsing). This is because a more zealous normalisation could provide better performance (by providing contemporary word forms), without the word forms themselves having to necessarily correspond to the correct ones.

To compare the methods for their conservativeness/zealousness, we align the output of each method with the source text and calculate (i) how often it changes a token that should have been kept as it is (Table 3), and (ii) how often it leaves a token untouched

Figure 3: Comparison in the number of ‘over-modified’ test set tokens for each method.

Figure 4: Comparison in the number of ‘under-modified’ test set tokens for each method.

that should be modified (Table 4). The identity function, rule-based system and ABA rarely over-modify, contrarily to SMT and NMT. Logically, the methods show the the inverse pattern for under-modification, with the identity and rule-based approaches being the most conservative and under-modifying the most. The SMT and NMT models under-modify at very similar rates, suggesting that performance differences could largely stem from over-modification rather than how much they under-modify. The best method, SMT, has the lowest rate of under-modification and a medium level of over-modification. ABA is interesting, because it under-modifies less than the baselines and yet does not over-modify as much as the MT approaches.

Adding the *Lefff*-based post-processing step has the effect of both correcting some over-modifications that were introduced and providing some normalisations for previously unmodified tokens, thereby significantly improving the processing of OOV words.

8.3. Qualitative analysis of approaches

In this section, we give an overview of the results of the best rule-based approach, ABA + *Lefff* and the best MT approach, SMT + *Lefff*, by comparing them using an alignment of the normalised versions of the dev data available at <https://igm.univ-mlv.fr/~gambette/2022Normalisation/>.

Unsurprisingly, given that the substitution rules are not contextual, ABA + *Lefff* makes many errors in ambiguous cases, such as *A* instead of *À*, *près* instead of

près, *voila* instead of *voilà*, or *mes feux redoublez* instead of *mes feux redoublés*. Taking into account frequency scores either for the word replacement or for the character transformation rules in the training data may help avoid those mistakes. ABA + *Lefff* is also very sensitive to mistakes in the training corpus. For example, it succeeds in transforming *auoient* into *avaient* but not *avoient*, whereas the SMT + *Lefff* succeeds. It also lacks some rules. For example it has no rule to normalise double consonants (for example *principalles* normalised into *principales*, *assouppit* into *assoupit*), whereas SMT + *Lefff* performs pretty well in this case. The SMT approach displays some more creative errors, but which appear easy spot if the normalised text is manually proof-read), e.g. *ma pēlée* transformed into *ma pmentsée*. It is also prone to deleting certain words such as determiners, possibly because in some contexts they are less probable according to the language model. Finally, considering the fact that often, when one of the two methods makes a mistake, the other one performs a correct normalisation, finding a relevant post-processing approach seems like a promising to increase the quality of the results.

9. Conclusion

We have presented *FREEMnorm*, a new benchmark for the normalisation of Early Modern French, and compared a range of normalisation methods, including an alignment-based approach and various MT-based approach, with SMT outperforming all other approaches. Adding a post-processing with a contemporary French lexicon systematically helps, particularly for OOV tokens. We compare the strengths of the different methods, with rule- and alignment-based approaches being more conservative and MT approaches being less so. While MT approaches achieve the best accuracy, a model such as the alignment-based ABA is possibly more adapted to pre-annotation as it offers a good compromise between making good normalisation choices without overly normalising tokens that should not have been modified. We release all our data, models and scripts to encourage further research on this topic and as resources for the digital humanities community.

A. ABA Normalisation Rules

The character transformation rules used in the second step of ABA include $\text{f} \rightarrow \text{s}$, $\text{ß} \rightarrow \text{ss}$, $\text{\&} \rightarrow \text{et}$; the resolution of letters with a tilde used to abbreviate an n or an m; $\text{sç} \rightarrow \text{s}$; final oing \rightarrow oin; final y \rightarrow i; sch \rightarrow ch; aye \rightarrow aie, oye \rightarrow oie. The obtained word is considered as an initial candidate followed by the supplementary candidates obtained with the following rules: ct \rightarrow t; vowel followed by dv \rightarrow same vowel followed by v; final ans \rightarrow ands, final ens \rightarrow ends, final ans \rightarrow ants, final ens \rightarrow ents; final ois \rightarrow ais (same with oit and oient); final ez \rightarrow és, final és \rightarrow ez; st \rightarrow t, est \rightarrow ét; as followed by m n q or t \rightarrow â followed by the same letter (same with es, is, os and us); y \rightarrow i; ü or eü \rightarrow u. Finally, for all generated candidates, the following transformation rules are applied: is \rightarrow î, ai \rightarrow aî, u \rightarrow v, v \rightarrow u, non final e not followed by s \rightarrow é.
