Fragments of bag relational algebra: Expressiveness and certain answers☆,☆☆

Marco Console, Paolo Guagliardo *, Leonid Libkin

School of Informatics, University of Edinburgh, United Kingdom

1. Introduction

While all relational database systems are based on the bag data model, much of theoretical research still views relations as sets. Recent attempts to provide theoretical foundations for modern data management problems under the bag semantics concentrated on applications that need to deal with incomplete relations, i.e., relations populated by constants and nulls. Our goal is to provide a complete characterization of the complexity of query answering over such relations in fragments of bag relational algebra. The main challenges that we face are twofold. First, bag relational algebra has more operations than its set analog (e.g., additive union, max-union, min-intersection, duplicate elimination) and the relationship between various fragments is not fully known. Thus we first fill this gap. Second, we look at query answering over incomplete data, which again is more complex than in the set case: rather than certainty and possibility of answers, we now have numerical information about occurrences of tuples. We then fully classify the complexity of finding this information in all the fragments of bag relational algebra.
and
\[
\max(\tilde{a}, q, D) = \max_{D \in [D]} #(\tilde{a}, q(D)).
\]

Under set semantics, \(\min(D, q, \tilde{a}) = 1\) means that \(\tilde{a}\) is a certain answer to \(q\) on \(D\), and \(\max(D, q, \tilde{a}) = 1\) means that \(\tilde{a}\) is a possible answer. On sets, these can be easily checked for positive relational algebra, but it is hard (coNP-complete and NP-complete, respectively) for full relational algebra [19]. This tells us that, in terms of relational algebra operations, selection, projection, Cartesian product and union are easy, but difference makes things hard. Our goal is to paint a similar picture for bags. The problems that we face are:

1. there are more operations that are included in bag relational algebra, and we have less understanding of them;
2. even for basic operations, there is very little knowledge of the complexity of answering queries over incomplete data.

We now explain these points in more detail.

Bag algebra fragments. Under set semantics, we have well understood fragments of relational algebra: SPC (select-project-Cartesian product) queries, positive relational algebra RA\(^+\) that adds union, and full relational algebra RA that adds difference. Moreover, intersection is expressible as the natural join of two relations over the same attributes. Under bag semantics, however, the situation is different:

- SPC queries follow their set-theoretic analogs but they keep duplicates.
- For union, there are two options: max-union, which takes the maximum number of occurrences of a tuple, and additive union, which adds up multiplicities (and corresponds to UNION ALL in SQL).
- Intersection (SQL’s INTERSECT ALL) takes the minimum number of occurrences of a tuple and it can no longer be expressed as a join in general.
- Difference (SQL’s EXCEPT ALL) subtracts multiplicities of tuples up to zero.
- There is the duplicate elimination operation, which sets the multiplicities of tuples to 1.

When the multiplicities of tuples in the input relations are at most 1, the bag operations of difference, intersection and max-union coincide with set-theoretic difference, intersection and union, respectively. SQL’s EXCEPT, INTERSECT and UNION (without the ALL modifier) are variants of difference, intersection and max-union, respectively, that treat input relations as sets by removing duplicates from them; UNION can also be seen as additive union followed by duplicate elimination.

The language RA of bag relational algebra consists of the following operations [4–6]:

- multiplicity-preserving versions of selection \((\sigma)\), projection \((\pi)\) and Cartesian product \((\times)\), which form the class of SPC queries;
- additive union \(\cup\) that adds up multiplicities of tuples; together with SPC queries it forms the positive relational algebra RA\(^+\);
- max-union \(\cup\) that keeps the maximum number of occurrences of a tuple;
- min-intersection \(\cap\) that keeps the minimum number of occurrences of a tuple;
- difference \(\setminus\) that subtracts the number of occurrences of a tuple up to zero, i.e., \(\#(\tilde{a}, R - R') = \max(#(\tilde{a}, R) - #(\tilde{a}, R'), 0)\);
- duplicate elimination \(\varepsilon\) that turns a bag into a set.

Example 1. For bags \(R = \{a, a, b, b, c\}\) and \(S = \{a, b, b\}\), we have:

\[
\begin{align*}
R \cup S &= \{a, a, b, b, b, b, b, b, c\}; \\
R \setminus S &= \{a, c\}; \\
R \cap S &= \{a, b, b\}; \\
\varepsilon(R) &= \{a, b, c\}; \\
\varepsilon(S) &= \{a, b\}.
\end{align*}
\]

We remark that, differently from additive union \(\cup\), the max-union operation \(\cup\) is not explicitly implemented in any standard query language. To see how it could be used in practice, consider a scenario with two sensors, \(r\) and \(s\), logging data about events \(a_1, a_2, \ldots\). etc. into unary relations \(R\) and \(S\), as follows: whenever an event \(a_i\) is detected by \(r\) (resp., \(s\)), an occurrence of \(a_i\) is added to \(R\) (resp., \(S\)). Now assume that for any given event, one of the sensors can reliably detect all of its occurrences, while the other may, or may not. Then, \(R \cup S\) correctly collates the data from the two sensors’ logs, returning all the reliably detected occurrences of every event, but \(R \cup S\) does not.

To understand how query answering behaves in the fragments of RA, we first need to understand their relative expressiveness. It might appear that these questions have already been answered in [5,20]. However, this was done in the context of nested relations, and the results used the power of nesting in an essential way. For the usual bag algebra with non-nested relations, as implemented in all DBMSs, these basic results are surprisingly lacking. Thus, as our first task, we shall produce a full picture of the expressiveness of bag relational algebra fragments (which will indeed be different from the known results in the nested case).

Incomplete information and bags. There is a much bigger variety of relational algebra fragments for bags, but little is known about finding \(\min(\tilde{a}, q, D)\) and \(\max(\tilde{a}, q, D)\) for queries in those fragments. We know that \(\min\) is easy to compute for RA\(^+\) queries and that for full RA the problem is computationally hard: checking whether \(\min(\tilde{a}, q, D) \geq n\) is NP-complete [19,21]. Checking whether \(\max(\tilde{a}, q, D) \geq n\) is NP-complete even for SPC queries [21]. The complexity of actually computing \(\min\) and \(\max\) (or, in terms of a decision problem, checking whether \(\min(D, q, D) = n\), and likewise for max) is still open.

Outline of the results. Our main results are summarized in Fig. 1.

Expressiveness We characterize the relative expressive power of RA fragments, as shown in the diagram. Furthermore, adding duplicate elimination to a fragment that does not have it results in a language that is strictly more expressive (than the original fragment), and incomparable with RA\(^+\) \(\{\}\) (i.e., RA\(^+\) with difference). The relative expressiveness of bag operations is indeed different from what was known in the nested relational case [5,6,20]. For example, over nested relations, adding min-intersection to the analog of RA\(^+\) suffices to express max-union, but in the usual relational algebra over bags these two operations are incomparable in their expressiveness.

Complexity of min For fragments in the shaded area, computing \(\min(\tilde{a}, q, D)\) is tractable, and it can be done by evaluating the query naively on the incomplete database. For all fragments outside the shaded area, and all fragments with duplicate elimination (from SPC\(\{\varepsilon\}\) to the full RA), the complexity is intractable: checking whether \(\min(\tilde{a}, q, D) \theta n\) is NP-complete when \(\theta\) is \(\leq\), coNP-complete when \(\theta\) is \(\geq\), and DP-complete when \(\theta\) is \(\neq\). Recall that DP is the class of problems that are the intersection of an NP problem and a coNP problem [22].

Complexity of max For all the fragments, inside and outside the shaded area, and with or without duplicate elimination, computing max is intractable: checking \(\max(\tilde{a}, q, D) \theta n\) is NP-complete when \(\theta\) is \(\geq\), coNP-complete when \(\theta\) is \(\leq\), and DP-complete when \(\theta\) is \(\neq\).
Organization. Bag relational algebra is defined in Section 2, and the relative expressive power of its fragments is studied in Section 3. Query answering over bags with nulls is discussed in Section 4, and its complexity is classified in Section 5. Concluding remarks are given in Section 6.

2. Bag relational algebra

We now describe the standard operations of bag relational algebra and provide their semantics [4–5, 20]. A bag is a collection of elements with associated multiplicities (numbers of occurrences); if an element b occurs n times in a bag B, we write \( \#(b, B) = n \). If \( \#(b, B) = 0 \), it means that b does not occur in B. Sets are just a special case when \( \#(b, B) \in \{0, 1\} \).

In a database D, each k-ary relation name R of the schema is associated with a bag \( R^k \) of k-tuples; we omit the superscript \( D \) whenever it is clear from the context. We assume that the attributes of a k-ary relation are 1, . . . , k, i.e., we adopt the unnamed perspective [18].

Syntax. The syntax of relational algebra (RA) expressions is defined as follows:

\[
\begin{align*}
\text{e, e'} &::= R \quad \text{(base relations)} \\
& \mid \sigma_{\alpha}(e) \quad \text{(selection)} \\
& \mid \pi_n(e) \quad \text{(projection)} \\
& \mid e \times e' \quad \text{(Cartesian product)} \\
& \mid e \lor e' \quad \text{(additive union)} \\
& \mid e \land e' \quad \text{(max-union)} \\
& \mid e \land e' \quad \text{(intersection)} \\
& \mid e - e' \quad \text{(difference)} \\
& \mid e(e) \quad \text{(duplicate elimination)}
\end{align*}
\]

where \( i \) and \( j \) in \( \sigma_{\alpha}(e) \) are positive integers, and \( \alpha \) in \( \pi_n(e) \) is a possibly empty tuple of positive integers.

The arity of RA expressions is defined as follows: for base relations, it is given by the schema; for \( \sigma_{\alpha}(e) \) and \( e(e) \), it is the arity of \( e \); for \( \pi_n(e) \), it is the arity of \( \alpha \); for \( e \times e' \), it is the sum of the arities of \( e \) and \( e' \); for \( e \lor e' \) with \( \bullet \in \{\lor, \land, \lor, \land, \land\} \), it is the arity of \( e \).

We then say that an RA expression is well-formed w.r.t. a schema if: it mentions only relation names from the schema; \( i \) and \( j \) in \( \sigma_{\alpha}(e) \) are less than or equal to the arity of \( e \); the elements of \( \alpha \) in \( \pi_n(e) \) are less than or equal to the arity of \( e \); the expressions \( e \lor e' \) with \( \bullet \in \{\lor, \land, \lor, \land, \land\} \) have the same arity. In the rest of the paper, we implicitly assume that we are always working with well-formed RA expressions.

Semantics. We give the semantics of (well-formed) RA expressions \( e \) by inductively defining the quantity \( \#(\bar{a}, e, D) \), which is the number of occurrences of a tuple \( \bar{a} \) (of appropriate arity) in the result of applying \( e \) to a database \( D \). This is done as follows:

\[
\begin{align*}
\#(\bar{a}, R^D) &= \#(\bar{a}, e, D) \quad \text{if } \bar{a}.i = \bar{a}.j \\
&= 0 \quad \text{otherwise}
\end{align*}
\]

\[
\begin{align*}
\#(\bar{a}, \sigma_{\alpha}(e), D) &= \sum_{\bar{a}': \pi_n(\alpha') = \bar{a}} \#(\bar{a}', e, D)
\end{align*}
\]

\[
\begin{align*}
\#(\bar{a}, \pi_n(e), D) &= \begin{cases} \#(\bar{a}, e, D) \cdot \#(\bar{a}', e', D) & \text{if } \#(\bar{a}, e, D) \\ 0 & \text{otherwise} \end{cases}
\end{align*}
\]

\[
\begin{align*}
\#(\bar{a}, e \lor e', D) &= \max\{\#(\bar{a}, e, D), \#(\bar{a}, e', D)\}
\end{align*}
\]

\[
\begin{align*}
\#(\bar{a}, e - e', D) &= \max\{\#(\bar{a}, e, D) - \#(\bar{a}, e', D), 0\}
\end{align*}
\]

\[
\begin{align*}
\#(\bar{a}, e(e), D) &= \min\{\#(\bar{a}, e, D), 1\}
\end{align*}
\]

where \( \bar{a}.i \) denotes the \( i \)th element of \( \bar{a} \), \( \pi_{i_1 \ldots i_k}(\bar{a}) \) is the tuple \( (\bar{a}.1, \ldots, \bar{a}.i_1) \), and the tuples \( \bar{a} \) and \( \bar{a}' \) in the rule for \( e \lor e' \) have the same arity as \( e \) and \( e' \), respectively.

Then, for an expression \( e \) and a database \( D \), we define \( e(D) \) as the bag of tuples \( \bar{a} \) of the same arity as \( e \) so that \( \#(\bar{a}, e(D)) = \#(\bar{a}, e, D) \).

3. Expressive power of bag relational algebra fragments

In this section, we study the relative expressive power of RA fragments. We present the results that justify the edges in Fig. 1, along with additional results that are not explicitly captured in that diagram.
We start by showing that extending positive relational algebra with max-union or intersection results in a more expressive fragment.

**Proposition 1.** RA⁺ ⊆ RA⁺[⋆] for ⋆ ∈ {∪, ∩}.

**Proof.** Trivially RA⁺[⋆] is at least as expressive as RA⁺, so we only need to show that there exists a query that is expressible in the former but not in latter. To this end, consider a schema consisting of two nullary relation symbols R and S, and suppose that R ⋈ S is expressible in RA⁺, i.e., there exists an RA⁺ expression e equivalent to R ⋈ S. For a database D, let m = |D| and n = |S|; then, |e(D)| = f(m, n), where f₀ = max and f₁ = min. Moreover, |e(D)| is expressible by a polynomial p_r ∈ N[m, n], because e ∈ RA⁺.

For n₀ ∈ N, we define the polynomial p ∈ N[m, n] such that p(n) = p_r(m, n₀) and distinguish the following two cases.

- When ⋆ = ∪, then n₀ = deg(p₁) ≥ deg(p₀). Then, p(n) = max(m, n₀) = n₀ for every m ∈ {0, . . . , n₀}. But this is impossible, as the unique polynomial p ∈ N[m, n] of degree at most n₀ that interpolates the n₀ + 1 data points ([i, n₀] | i = 0, . . . , n₀) is the constant function p(m) = n₀, and p(n) = p(m) for m > n₀.

- When ⋆ = ∩, then n₀ be a positive integer. We have deg(p₁) ≥ 1, as p(n) = min(m, n₀) = n₀ > 0 for every m ≥ n₀, while p(0) = 0. Then p is strictly increasing in the interval [0, +∞), since its coefficients are in N. But this is impossible because p(m) = n₀ for every m ≥ n₀. □

The proof of Proposition 1 also applies to show the following.

**Corollary 1.** SPC ⊆ SPC[⋆] for ⋆ ∈ {∪, ∩}.

We now show that additive union increases the expressive power of SPC(∩) and SPC(∪).

**Proposition 2.** SPC[⋆] ⊆ RA⁺[⋆] for ⋆ ∈ {∪, ∩}.

The proof of the above result is based on the fact that, on databases consisting of nullary relations of size 1, there are RA⁺ expressions whose result size is greater than 1, whereas every SPC(∪, ∩) expression can only yield a (nullary) relation of size 1, as the following lemma shows.

**Lemma 1.** Let D be a database over a schema consisting only of nullary relation names and such that R₀ = {()} for every relation name R in the schema. Then, for every SPC(∪, ∩) expression e, it is the case that e(D) = {()}.  

**Proof.** Let e be an SPC(∪, ∩) expression over the schema of D. Observe that all subexpressions of e are nullary and, since there are no attributes, one of them can be a selection. Moreover, projection will be over an empty list of attributes and so it can be discarded. Thus, assuming w.l.o.g. that there is no projection, we proceed by induction on the structure of e to show that e(D) = {()}.  

The base case is when e is a relation name R; then trivially e(D) = {()}. For the inductive step, we have that e = e₁ ⋈ e₂ with ⋆ ∈ {∪, ∩, ×} and, by the inductive hypothesis, e₁(D) = e₂(D) = {()}. Then, from the semantics of ⋆, for ⋆ ∈ {∪, ∩}, we get e(D) = e₁(D) ⋈ e₂(D) = {()}. □

**Proof of Proposition 2.** Let ⋆ ∈ {∪, ∩}. Trivially RA⁺[⋆] is at least as expressive as SPC[⋆], thus we only need to show that there is a query expressible in the former but not in latter. To this end, consider a schema consisting of a nullary relation name R, and suppose that e = RwR (which, in particular, is an RA⁺ expression) is expressible in SPC[⋆], i.e., there exists an SPC[⋆] expression e’ equivalent to e. Towards a contradiction of this equivalence, let D be a database where R₀ = {()}. Then, since e’ is an SPC[∪, ∩] expression, by Lemma 1 we have that e’(D) = {()}, whereas e(D) = {()}. □

In particular, the proof of Proposition 2 also applies to show the following.

**Corollary 2.** SPC ⊆ RA⁺.

Next, we will show that ∪ increases the expressive power of RA⁺[∩] and ∩ increases the expressive power of RA⁺[∪]. In turn, this implies that ∪ and ∩ are incomparable operations.

**Proposition 3.** RA⁺[⋆] ⊆ RA⁺[∪, ∩] for ⋆ ∈ {∪, ∩}.

To prove the above, we need some additional notions and lemmas. We start by introducing a special syntactic form for RA⁺[∩] expressions.

**Definition 1.** An RA⁺[∩] expression is in intersection normal form (∩-NF) if it is of the form e₁ ∩ · · · ∩ eₙ where each eᵢ is an RA⁺ expression. Observe that this is well defined because ∩ is commutative and associative.

**Lemma 2.** Every RA⁺[∩] expression over nullary relation names can be equivalently rewritten to ∩-NF.

**Proof.** Let e be an RA⁺[∩] expression over nullary relation names. As before, note that all subexpressions of e are nullary and, since there are no attributes, none of them can be a selection. Moreover, projection will be over an empty list of attributes and therefore it can be discarded. Assuming w.l.o.g. that there is no projection, we proceed by induction on the structure of e.

**Base case:** e is R. Then R ∩ R is obviously equivalent to e and in ∩-NF.

**Inductive step:** e is e’ ⋆ e’’ with ⋆ ∈ {∪, ×}. By the induction hypothesis, there are ∩-NF expressions e’₁ ⋆ · · · ⋆ e’ₘ and e’’₁ ⋆ · · · ⋆ e’’ₙ equivalent to e’ and e’’, respectively. Then, the following ∩-NF expression:

\[ \bigcap_{i=1}^{m} \bigcap_{j=1}^{n} (e’ᵢ ⋆ e’’ⱼ) \]

is equivalent to e because:

\[ f₁(\min(x₁, \ldots, xₘ), \min(y₁, \ldots, yₙ)) \]

\[ = \min(f₁(x₁, y₁), \ldots, f₁(xₘ, yₙ), f₂(x₁, y₁), \ldots, f₂(xₘ, yₙ)) \]

where:

- f₁(x, y) = x ⋆ y and f₂(x, y) = x + y; and,
- for any given database D, we have that each xᵢ = |e’ᵢ(D)| and each yⱼ = |e’’ⱼ(D)|. □

The proofs of the next two lemmas can be found in Appendix.

**Lemma 3.** Let D be a database over a schema with a nullary relation symbol R, and let e be an RA⁺[∪] expression that mentions only R. Then, |e(D)| ≥ |R|.

**Lemma 4.** Let D be a database over a schema consisting of two nullary relation symbols R and S, and let e be an RA⁺[∪] expression that mentions both R and S. Then, |e(D)| ≥ |R| and |e(D)| ≥ |S|.

We are now ready to prove the result on the expressiveness of RA⁺[∪, ∩] stated earlier.
Proof of Proposition 3.

- $\mathsf{RA}^+\{\cup\} \subseteq \mathsf{RA}^+\{\cap, \cup\}$

Trivially $\mathsf{RA}^+\{\cap, \cup\}$ is at least as expressive as $\mathsf{RA}^+\{\cup\}$; therefore, we only need to show that there exists a query expressible in $\mathsf{RA}^+\{\cap, \cup\}$ that is not expressible in $\mathsf{RA}^+\{\cup\}$. To this end, consider a schema consisting of two nullary relation symbols $R$ and $S$, and the $\mathsf{RA}^+\{\cap, \cup\}$ expression $e = R \cap S$. Towards a contradiction, suppose that $e$ is expressible in $\mathsf{RA}^+\{\cup\}$, i.e., there exists an $\mathsf{RA}^+\{\cup\}$ expression $e'$ equivalent to $e$.

Let us first consider the case when $e'$ mentions only either $R$ or $S$; w.l.o.g., say $R$. Take $D$ such that $|R^0| > |S^0|$; then $|e(D)| = |S^0|$ and $|e'(D)| > |R^0|$ by Lemma 3. Therefore, $|e(D)| > |e'(D)|$, which contradicts the equivalence of $e$ and $e'$.

When $e'$ mentions both $R$ and $S$, we can again take $D$ such that $|R^0| > |S^0|$, which leads to the same contradiction, since $|e(D)| = |S^0|$ and $|e'(D)| > |R^0|$ by Lemma 4.

- $\mathsf{RA}^+\{\cap\} \subseteq \mathsf{RA}^+\{\cap, \cup\}$

Trivially $\mathsf{RA}^+\{\cap, \cup\}$ is at least as expressive as $\mathsf{RA}^+\{\cap\}$; therefore, we only need to show that there exists a query expressible in $\mathsf{RA}^+\{\cap, \cup\}$ that is not expressible in $\mathsf{RA}^+\{\cap\}$. To this end, consider a schema consisting of two nullary relation symbols $R$ and $S$, and the $\mathsf{RA}^+\{\cap, \cup\}$ expression $e = R \cup S$. Towards a contradiction, suppose that $e$ is expressible in $\mathsf{RA}^+\{\cap\}$, i.e., there exists an $\mathsf{RA}^+\{\cap\}$ expression $e'$ equivalent to $e$. By Lemma 2, $e'$ is equivalent to an expression of the form $e_1 \cap \cdots \cap e_k$ where each $e_i$ is an $\mathsf{RA}^+\{\cap\}$ expression. Then, for every database $D$, whenever $m = |R^0|$ and $n = |S^0|$ we have that

$$\max(m, n) = \min(p_{1}, \ldots, p_{k})$$

where each $p_i$ is a bivariate polynomial in $\mathbb{N}^+[m, n]$. Let $d$ be the maximum degree of a polynomial among $p_1, \ldots, p_k$, and let $n_0 = (d + 1)k + 1$. Then for each $m < n_0$ we have $n_0 = \max(m, n_0) = \min(p_1(m, n_0), \ldots, p_k(m, n_0))$. Consider now univariate polynomials $p_i(i) = p_i(m, n_0)$ for $i \leq k$. We have $0 = n_0 - n_0 = \min(p_1(i), \ldots, p_k(i))$ for all $m < n_0$. By pigeonhole, it means that there is a polynomial $p_j(i)$ and at least $d + 1$ distinct values $m_1, \ldots, m_{d+1}$ smaller than $n_0$ such that $p_j(m_i) = \ldots = p_j(m_{d+1}) = 0$. Since the degree of $p_j$ is at most $d$, this implies that $p_j(m)$ is identically zero, and thus $p_j(m, n_0) = n_0$ for all $m$.

Now, using $\max(m, n) = \min(p_1(m, n), \ldots, p_k(m, n))$, we have

$$n_0 + 1 = \max(n_0 + 1, n_0) = \min(p_1(n_0 + 1, n_0), \ldots, p_k(n_0 + 1, n_0)) \leq p_i(n_0 + 1, n_0) = n_0,$$

which contradicts the assumption that $\cup$ is expressible in $\mathsf{RA}^+\{\cap\}$. \hfill \square

The following is a direct consequence of Proposition 3.

Corollary 3. $\mathcal{L}\{\cup\}$ and $\mathcal{L}\{\cap\}$ are incomparable, for $\mathcal{L} \in \{\text{SPC}, \mathsf{RA}^+\}$.

Finally, we show that with additive union and difference one can express both intersection and max-union, therefore $\mathsf{RA}^+\{\cdots\}$ is the most expressive fragment of RA without duplicate elimination.

Proposition 4. $\mathsf{RA}^+\{\cap, \cup\} \subseteq \mathsf{RA}^+\{\cdots\}$.

Proof. Let $e \in \mathsf{RA}^+\{\cap, \cup\}$; by induction on the structure of $e$ we will show that there exists an expression $e' \in \mathsf{RA}^+\{\cdots\}$ that is equivalent to $e$. The base case is when $e = \mathsf{RA}^+$, which is trivially also in $\mathsf{RA}^+\{\cdots\}$. For the inductive step, let $e = e_1 \oplus e_2$, with $e_1, e_2 \in \mathsf{RA}^+\{\cap, \cup\}$ and $\in \{\cap, \cup\}$. By the induction hypothesis, there exist $e', e'' \in \mathsf{RA}^+\{\cdots\}$ such that $e' \equiv e_i$ for $i = 1, 2$. Consider the $\mathsf{RA}^+\{\cdots\}$ expressions $e_1 = e_1 - (e_1 - e_2)$ and $e_2 = e_1 \cup (e_1 - e_2)$; we will show that $e' \equiv e_1 \cup e_2 = e$ for $e \in \{\cap, \cup\}$. Towards this end, let $D$ be a database and let $\bar{a}$ be a tuple; moreover, let $m = \#(\bar{a}, e_1, D)$ and $n = \#(\bar{a}, e_2, D)$. Then, we have the following:

$$k_1 = \#(\bar{a}, e_1, D) = \#(\bar{a}, e_1', D) - \#(\bar{a}, e_1', D) - \#(\bar{a}, e_2', D)) = (m - (m - n))$$

$$k_2 = \#(\bar{a}, e_2, D) = \#(\bar{a}, e_2', D) + \#(\bar{a}, e_2', D) - \#(\bar{a}, e_2', D)) = (m - (n - m))$$

If $m \geq n$, we have that $0 \leq m - n = m - n \leq m$ and $n = 0$; therefore $k_1 = m - (m - n) = n$ and $k_2 = m$. Otherwise, when $n > m$, we have that $m - n = 0$ and $n - m = n - m$; thus $k_1 = m - 0 = m$ and $k_2 = m + m - n = m$. Thus, $k_1 = \min(m, n)$ and $k_2 = \max(m, n)$.

Now, since $e_1 \equiv e_i$ and $e_2 \equiv e_i$ by the induction hypothesis, both expressions $\#(\bar{a}, e_1, D)$ and $\#(\bar{a}, e_2, D)$ are identical, and as $D$ and $\bar{a}$ were chosen arbitrarily, $e \equiv e_1 \cup e_2$. This proves that $\mathsf{RA}^+\{\cap, \cup\} \subseteq \mathsf{RA}^+\{\cdots\}$.

We are left to show that the containment is strict. This follows from the fact that every query $q$ expressible in $\mathsf{RA}^+\{\cap, \cup\}$ is monotonic, that is, $q(D) \subseteq q(D')$ for all databases $D$ and $D'$ such that $D \subseteq D'$. However, in $\mathsf{RA}^+\{\cdots\}$, one can express queries that are not monotonic. Consider $e = \bar{R} - \bar{S}$ over unary relation names $\bar{R}$ and $\bar{S}$, and let $D = (\bar{R}(a), \bar{S}(b))$ and $D' = (\bar{R}(a), \bar{S}(b))$; then, $D \subseteq D'$ but $e(D) = (\bar{R}(a)) \not\subseteq e(D') = \emptyset$. \hfill \square

Then, obviously, we immediately get the following.

Corollary 4. $\mathsf{RA}^+\{\cdots, \epsilon\}$ and RA have the same expressive power.

We conclude this section by showing that adding duplicate elimination to a fragment that does not already have it increases its expressive power.

Proposition 5. $\mathcal{L} \subseteq \mathcal{L}(\epsilon)$ for every fragment $\mathcal{L}$ of RA without duplicate elimination.

The proof of Proposition 5 is based on the fact that, on databases with relations of even size, every $\mathsf{RA}^+\{\cdots\}$ expression can only yield a relation of even size, as the following lemma shows.

Lemma 5. Let $\mathcal{L}$ be a fragment of bag relational algebra without duplicate elimination, let $e$ be an $\mathsf{RA}^+\{\cdots\}$ expression, and let $D$ be a database such that, for every relation name $R$, the number of occurrences of every tuple in $R^0$ is even. Then, the number of occurrences of every tuple in $e(D)$ is even.

Proof. Let $\bar{a}$ be a tuple that occurs $k$ times in $e(D)$, and let $k > 0$ (for $k = 0$ we have nothing to show). By induction on the structure of $e$, we will show that $k$ is even.

Base case: $e$ is a relation name $R$. Then, $k = \#(\bar{R}, \bar{R}^0)$ is even by assumption.

Inductive step:

- $e = \pi_\alpha(e')$. Then, $k$ is the sum of the number of occurrences of all tuples $\bar{a'} \in e'(D)$ such that $\pi_\alpha(\bar{a'}) = \bar{a}$. The number of occurrences of every tuple in $e(D)$ is even by the induction hypothesis, hence $k$ is even as well.
* e = σ_m(e'). Then k = #(ã, e', D), which is even by the induction hypothesis.
* e = e_1 × e_2. Then, there are tuples ̃_1 ∈ e_1(D) and ̃_2 ∈ e_2(D) such that ̃_1 = ̃_1̃_2 and k = m · n, where m = #(ã, e_1, D) and n = #(ã, e_2, D). As k > 0, both m and n are positive and, by the induction hypothesis, even. Hence, k is even as well.
* e = e_1 ∪ e_2. Then, k = m + n where m = #(ã, e_1, D) and n = #(ã, e_2, D). Since k > 0, at least one of m and n must be positive. Assume w.l.o.g. that m > 0; then, m is even by the induction hypothesis. If n = 0, then k = m is even; otherwise, n is even by the induction hypothesis as well, and therefore k is the sum of two positive even numbers, which is obviously even.

\[
\text{Proof of Proposition 5. Let } \mathcal{C} \text{ be a fragment of bag relational algebra without duplicate elimination. Clearly, } \mathcal{L}(e) \text{ is at least as expressive as } \mathcal{C}, \text{ so we only need to show that there exists a query that is expressible in the former but not in latter. To this end, consider a schema consisting of a nullary relation } R \text{ and take any database } D \text{ such that } |D| \text{ is a positive even number. Then, for every } \mathcal{C} \text{ expression over } R, \text{ we have that } |e(D)| \text{ is even by Lemma 5. Hence, the } \mathcal{L}(e) \text{ expression } v(R) \text{ is not expressible in } \mathcal{C}, \text{ since } |e(R)| = 1. \]

4. Certain and possible answers under bag semantics

Dealing with incomplete information is a recurring topic in many different areas of logic and computer science. In database theory, the main way to deal with the lack of information is via incomplete databases. Intuitively, an incomplete database D is a compact representation of a possibly infinite collection |D| of complete databases, which define the semantics of D.

In this paper, we use incomplete databases with marked (or labeled) nulls. This model of incompleteness is very common in the database literature [17,18] and naturally occurs in many different scenarios, e.g., in data exchange and integration (cf. [24–26]). In this model databases are populated by constants and nulls, coming from two disjoint and countably infinite sets denoted by Const and Null, respectively. More formally, a k-ary relation is a finite bag of k-ary tuples over Const ∪ Null. A database D then maps each k-ary relation symbol R in the schema to a k-ary bag relation |D|. Given a database D = (|D|, . . . , |D|), we write Const(D) and Null(D) for the set of constants and nulls occurring in the |D|’s, respectively. The active domain of D is the set Const(D) ∪ Null(D), denoted by adom(D). We say that D is complete if Null(D) = ∅.

The semantics |D| of a database D is defined by means of valuations. A valuation v is a map v: Null(D) → Const, and the result of applying v to D is the complete database v(D) obtained by replacing each null ⊥ ∈ Null(D) with v(⊥). Observe that applying v to each relation |D| in D preserves multiplicities, i.e., for each relation name R in the schema and each tuple ̃ ∈ |D| the following equality holds:

\[
\#(C, R^{(D)}) = \sum_{v(⊥) = ̃} \#(ã, R^{(D)}).
\]

The set |D| is defined as |D| = {v(D) | v is a valuation}.

When relations are sets, the standard way to answer a query q on an incomplete database D is to compute certain answers, i.e., tuples that are in q(D’) for every D’ ∈ |D|, and possible answers, i.e., tuples that are in q(D’) for some D’ ∈ |D|.

relations are bags, however, one must also take multiplicities into account. In what follows, this is done by computing the minimum and maximum number of occurrences of a tuple in the answers across all databases in |D| (cf. [21]). Let D be a database, let q be a relational algebra expression of arity n, and let ̃ ∈ Const(D)^n be a tuple of constants, we define min(̃, q, D) and max(̃, q, D) as follows:

\[
\min(̃, q, D) = \min_{D' \in |D|} \#(ã, q(D')) \quad \text{and} \\
\max(̃, q, D) = \max_{D' \in |D|} \#(ã, q(D')).
\]

Intuitively, min(̃, q, D) and max(̃, q, D) are extensions of certain and possible answers to bag databases. Indeed, min(̃, q, D) ≥ 1 if and only if ̃ is in q(D’) for every D’ ∈ |D| (and thus it is a certain answer), and max(̃, q, D) ≥ 1 if ̃ is in q(D’) for some D’ ∈ |D| (and thus it is a possible answer).

Thus, from now on we assume min(̃, q, D) and max(̃, q, D) as our standard notion of query answers and study their complexity. More specifically, we will focus on data complexity, that is, computing min(̃, q, D) and max(̃, q, D) for a fixed query q. Depending on the type of comparison we use, several decision problems arise from the computation of min and max. These decision problems are defined as follows.

| PROBLEM: | \min^\theta[q], for \theta = [>, =, <] and a query q of arity n. |
| INPUTS: | an incomplete database D, a tuple ̃ ∈ Const(D)^n, a non-negative integer k. |
| QUESTION: | is \min(̃, q, D) \theta k? |

| PROBLEM: | \max^\theta[q], for \theta = [>, =, <] and a query q of arity n. |
| INPUTS: | an incomplete database D, a tuple ̃ ∈ Const(D)^n, a non-negative integer k. |
| QUESTION: | is \max(̃, q, D) \theta k? |

Whether the number k is represented in unary or binary form does not matter: the results will be the same regardless. All tractability results are shown assuming binary representation, and all matching hardness results will be proved for the case when k is represented in unary. The choice of inequalities, i.e., < vs \leq or > vs \geq, is not important: since k is an integer, \leq k is the same condition as < k + 1.

As for the case of certain and possible answers, the complexity of the above problems depends on the fragment of RA in which the query q is expressed. While for some of these fragments the problems can be proved to be intractable, there are fragments of RA for which computing min(̃, q, D) is tractable and can actually be done via naive evaluation. The naive evaluation of a query q of arity n on a bag database D is defined as the bag obtained by assuming that each null value in Null(D) is a distinct constant and evaluating q directly over D. In what follows, we will denote by naive(̃, q, D) the number of occurrences of a tuple ̃ ∈ Const(D)^n in the result of the naive evaluation of an RA query q on an incomplete database D. It is well known that naive(̃, q, D) can be computed in DLOGSPACE in data complexity [5,6].

Example 2. On a database with relations R = {a, ⊥_1, ⊥_2} and S = {⊥_1, ⊥_2}, the naive evaluation of σ_{⊥_2}(R ∩ S), σ(R) and R ∩ S gives {⊥_1, ⊥_1), (⊥_1, ⊥_1)}, {a, ⊥_1} and {⊥_1}, respectively.
5. Complexity of certain and possible answers

We now turn our attention to the complexity of evaluating bag relational algebra expressions on incomplete databases, that is, solving the problems MIN$^\bullet[q]$ and MAX$^\bullet[q]$ for queries in various fragments of RA. As already explained, these problems are natural bag analogs of the notions of certainty and possibility over set databases.

In Section 5.1, we first provide upper and lower bounds for full RA. When the relation $\theta$ is $<$ or $>$, the results are easily derivable from the results for the set case in [19]; we complement them with the exact complexity for equality.

After introducing our technical framework in Section 5.2, we then focus – in Section 5.3 – on the problem MIN$^\bullet[q]$, proving the exact tractability boundary shown in Fig. 1. We start by showing that in all fragments up to RA$^+$ (\(|\cap|\)), the value of min can be computed by naive evaluation of queries, which extends a result in [21]. We then show that beyond this fragment the problem becomes intractable: NP-complete for $<$, coNP-complete for $>$, and DP-complete for $\equiv$. In particular, we show that the problem is intractable for all fragments containing SPC$[\cup]$, and all fragments containing SPC$[\varepsilon]$.

Next, in Section 5.4, we look at MAX$^\bullet[q]$. It was shown in [21] that for $>$ the problem is NP-complete, even for very simple queries. Here, we complete the picture and settle the case for $\equiv$, even when $q$ is a query that simply returns a relation from the database.

Finally, in Section 5.5, we discuss what happens with more complex selection conditions in queries.

5.1. Upper and lower bounds for full RA

Before delving into the complexity of the different fragments of RA, we briefly look at the complexity of evaluating general expressions. First, observe that RA queries are generic, i.e., invariant under permutations of the domain. In the bag case, this is stated as follows.

Proposition 6. Let $D$ and $D'$ be complete databases, let $\rho$ be a bijection between $\text{adom}(D)$ and $\text{adom}(D')$ such that $D' = \rho(D)$, and let $q \in RA$ be a query of arity $n$. Then, $\#(\bar{\alpha}, q, D) = \#(\rho \bar{\alpha}, q, D')$ for every tuple $\bar{\alpha} \in \text{adom}(D)^n$.

Proof. By induction on the structure of $q$.

Base case:
- $q = R$. Trivial.

Inductive step:
- $q = q_1 \circ (q_2')$. Suppose such $\rho$ exists. Since $\rho$ is a bijection, $\bar{\alpha}$ satisfies $q_1$ if and only if $\rho \bar{\alpha}$ does. If $\bar{\alpha}$ does not satisfy $q_1$ then $\#(\bar{\alpha}, q, D) = \#(\rho \bar{\alpha}, q, D') = 0$. Suppose now that $\bar{\alpha}$ satisfies $q_1$. From the inductive hypothesis, we can conclude that $\#(\bar{\alpha}, q, D) = \#(\rho \bar{\alpha}, q, D')$. Hence $\#(\bar{\alpha}, q, D) = \#(\rho \bar{\alpha}, q, D')$.
- $q = \pi_q(q')$. Assume that $q'$ has arity $m$ and suppose that there exists a bijection $\rho$ with the properties defined above. Let $\bar{a}$ and $\bar{a}'$ be two tuples of arity $m'$ and $m''$ respectively, such that $\bar{a} = \bar{a} \circ \bar{a}'$. Then $\#(\bar{a}, q, D) = \#(\rho \bar{a}, q, D') = \#(\bar{a}', q, D')$. From the inductive hypothesis, $\#(\bar{a}, q, D) = \#(\rho \bar{a}, q, D')$ and $\#(\bar{a}', q, D) = \#(\rho \bar{a}', q, D')$. The claim follows from $\rho \bar{a} = \rho \bar{a} \circ \rho \bar{a}'$.
- $q = q' \times q''$. Assume that $q'$ has arity $m'$, $q''$ has arity $m''$, and suppose that there exists a bijection $\rho$ with the properties defined above. Let $\bar{a}_1$ and $\bar{a}_2$ be two tuples of arity $m'$ and $m''$ respectively, such that $\bar{a}_1 = \bar{a}_1 \circ \bar{a}_2$, then $\#(\bar{a}, q, D) = \#(\rho \bar{a}_1, q, D) \times \#(\rho \bar{a}_2, q', D')$. From the inductive hypothesis, $\#(\bar{a}_1, q, D) = \#(\rho \bar{a}_1, q, D')$ and $\#(\bar{a}_2, q', D) = \#(\rho \bar{a}_2, q', D')$. The claim follows from $\rho \bar{a} = \rho \bar{a}_1 \circ \rho \bar{a}_2$.
- $q = \varepsilon(q')$. By the inductive hypothesis, we have that $\#(\bar{a}, q', D) = \#(\rho \bar{a}, q', D')$. Then the claim follows from the definition of $\varepsilon$.

Intuitively, the above tells us that we need to take into account only finitely many valuations in order to compute the values in $(1a)$ and $(1b)$. Upper bounds of NP, coNP, and DP follow straightforwardly.

Proposition 7. Let $q$ be an expression in RA. Then:
- $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ are in NP;
- $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ are in coNP;
- $\text{MIN}^+\bullet[q]$ and $\text{MAX}^+\bullet[q]$ are in DP.

Proof. Let $D$ be an incomplete bag database, let $\bar{a}$ be a tuple in $\text{adom}(D)$, and let $k$ be a positive integer. Assume a set $C \subseteq Const$ such that $C$ is disjoint with $\text{adom}(D)$ and the cardinality of $C$ is the same as the cardinality of Null$(D)$. Let $V$ be the set of valuations for Null$(D)$ defined as follows: $V := \{v \mid \text{range}(v) \subseteq (\mathcal{C} \cup \text{Const})\}$. Clearly, for each $D' \subseteq D$, there exists a valuation $v \in V$ and a bijection $\rho$ from $\text{adom}(v)$ to $\text{adom}(D')$ such that $\rho$ is the identity over $\text{Const}(D)$ and $\rho(v(D)) = D'$. Using this observation, to check whether $\text{min}(\bar{a}, q, D) < k$ we can simply guess a valuation $v' \in V$ such that $\#(v' \bar{a}, q, v(D)) < k$. If such valuation exists, $v(D)$ is itself a witness of $\text{min}(\bar{a}, q, D) < k$. If such valuation does not exist, due to Proposition 6 we can conclude that there exists no $v'(D) \subseteq D$ such that $\#(v' \bar{a}, q, v(D)) < k$. A similar technique can be used to check whether $\text{max}(\bar{a}, q, D) > k$.

From these considerations we can conclude what follows. In order to solve $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ for input $D$ and $k$, one can simply guess a valuation $v$ for Null$(D)$ and check whether $\#(v \bar{a}, q, v(D)) < k$ and $\#(v \bar{a}, q, v(D)) > k$ respectively. To solve $\text{MIN}^\bullet[q]$, one can guess a valuation $v$ for Null$(D)$ such that $\#(v \bar{a}, q, v(D)) < k + 1$ and use it as a counterexample for $\text{min}(\bar{a}, q, D) > k$. Similarly, $\text{MAX}^\bullet[q]$ can be solved by guessing a valuation $v$ for Null$(D)$ such that $\#(v \bar{a}, q, v(D)) > k – 1$ and use it as a counterexample for $\text{max}(\bar{a}, q, D) < k$. Finally, to solve $\text{MIN}^\bullet[q]$, one can simply solve an instance of $\text{MIN}^\bullet[q]$ with input $D$, $a$, and $k + 1$, and an instance of $\text{MIN}^\bullet[q]$ with input $D$, $a$, and $k – 1$. The same technique can be used to solve $\text{MAX}^\bullet[q]$.

To prove the claim, we observe the following. For a given valuation $v$, checking whether $\#(v \bar{a}, q, v(D))$ can be done in $\text{DLocSpace}$ in the size of $D$ for $q$ in RA and $\theta \in \{<, >\}$. Moreover, valuations for Null$(D)$ can be guessed using a number of bits that is polynomial in the size of $D$.

For general RA expressions, all of these problems are complete in their respective classes.

Proposition 8. Let $q$ be an expression in RA. Then:
- $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ are NP-hard;
- $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ are coNP-hard;
- $\text{MIN}^\bullet[q]$ and $\text{MAX}^\bullet[q]$ are DP-hard.
Proof. The results for < and > follow directly from the fact that set databases can be simulated by bag databases. Hence, the hardness results presented in [19] apply. For =, we can show a reduction from a very well known DP-complete problem; see Theorem 2 for the case of MIN^*[q] and Theorem 4 for the case of MAX^*[q]. □

Despite these high bounds, one may expect that some fragments of RA will behave better; this is what we investigate next.

5.2. Technical tools

To prove our results, we will use reductions from two well-known decision problems: satisfiability (SAT) and satisfiability–unsatisfiability (SAT-UNSAT) of propositional formulae in conjunctive normal form (CNF). We use the following standard terminology:

- a literal is a propositional variable or its negation;
- a clause is a (non-empty) disjunction of literals;
- a k-CNF formula is a conjunction of clauses, where each clause consists of exactly k distinct literals.

We also assume that complementary literals (i.e., a propositional variable and its negation) do not appear in the same clause; this is without loss of generality, as such clauses can be removed without compromising equivalence to the original formula. Thus, we consider k-CNF formulae where each clause mentions precisely k distinct variables.

We write Var(ϕ) and |ϕ| for the set of variables and the number of clauses of ϕ, respectively. A truth assignment for ϕ is a function from Var(ϕ) to either t (true) or f (false). The formula ϕ is satisfiable if there exists a truth assignment that makes all of its clauses true.

Example 3. The following 3-CNF formula

\[ ϕ = \neg x_1 \lor x_2 \lor x_4 \land (x_1 \lor \neg x_2 \lor \neg x_3) \]

has two clauses, C₁ and C₂, each consisting of three literals. We have Var(ϕ) = {x₁, x₂, x₃, x₄} and |ϕ| = 2. The formula is satisfiable because there is a truth assignment that makes both C₁ and C₂ true; e.g., the one mapping every variable in Var(ϕ) to t.

We let k-SAT refer to the problem of checking whether a given k-CNF formula is satisfiable; this problem is well known to be NP-complete for k ≥ 3. Given two k-CNF formulae ϕ and ψ, SAT-UNSAT is the problem of checking whether ϕ is satisfiable while ψ is not. For k ≥ 3, this is known to be DP-complete [22].

In our reductions, we will use CNF formulae encoded as relations. To this end, we assume that formulae are built from a countably infinite and linearly ordered set Var of propositional variables. Assuming a bijection ρ from Var to Null, for each variable x ∈ Var we define the pairs:

\[ \bar{u}^x_0 = (0, ρ(x)), \]

\[ \bar{u}^x_1 = (ρ(x), 1). \]

Observe that \( \bar{u}^x_0 \) and \( \bar{u}^x_1 \) do not unify; there exists no valuation v of nulls such that \( v(\bar{u}^x_0) = v(\bar{u}^x_1) = (0, 1) \). We denote concatenation of tuples, in particular of pairs of the above form, by juxtaposition; for example, \( \bar{u}^{x_1}_0 \bar{u}^{x_2}_0 \) is the tuple \( (0, ρ(x), ρ(y), 1, ρ(z), 1) \).

Given a k-CNF formula ϕ, with each clause C of ϕ we associate a relation enc(C) of arity 2k constructed as follows:

1. For each truth assignment τ that makes C true, we add a single occurrence of the tuple \( \bar{u}_{τ(1)} \ldots \bar{u}_{τ(k)} \), where each \( \bar{u}_{τ(i)} \) is equal to \( \bar{u}^x_0 \) if \( τ(x_i) = t \) and to \( \bar{u}^x_1 \) if \( τ(x_i) = f \), and the variables are considered in the order we assumed on Var.
2. We then remove duplicates from the resulting relation, which amounts to considering only truth assignments that are unique with respect to what they assign to the variables mentioned in the clause C we are encoding.

If the clauses of ϕ are C₁, . . . , Cₘ, we define \( enc(ϕ) = \{ \bigcup_{i=1}^m enc(C_i) \} \). Note that the number of tuples in each \( enc(C_i) \) is exactly \( 2^k - 1 \) and so the total number of tuples in \( enc(ϕ) \) is \( |ϕ|(2^k - 1) \). Thus, when \( k \) is considered fixed, the size of \( enc(ϕ) \) is polynomial w.r.t. the size of ϕ.

Example 4. The encoding \( enc(ϕ) \) of the 3-CNF formula (2), assuming the ordering \( x_1 < x_2 < x_3 < x_4 \) and the mapping \( ρ(x_i) = i \) for \( i \in \{1, \ldots, 4\} \), is as follows:

The relations \( R_0 \) enjoy the following properties that will be central in our proofs.

Lemma 6. For every k-CNF formula ϕ, all of the following hold:

(a) Let \( R \) be the relation that encodes a clause of ϕ. Then, for every valuation v of nulls, \#((0, 1)^k, v(R)) ≤ 1.

(b) Let v be a valuation with range in \{0, 1\}, and let τ be the truth assignment such that, for each x ∈ Var(ϕ), \( τ(x) = t \) iff \( v(ρ(x)) = 1 \). Then, \( τ \) makes a clause C of ϕ true if and only if \#((0, 1)^k, v(R)) = 1, where \( R = enc(C) \).

(c) There is a truth assignment satisfying exactly m clauses of ϕ if and only if there is a valuation v with range in \{0, 1\} such that \#((0, 1)^k, v(R)) = m.

(d) For every valuation v, there is a valuation \( v' \) with range in \{0, 1\} such that \#((0, 1)^k, v(R)) ≥ \#((0, 1)^k, v(R'))

Proof.

(a) By construction, all tuples in R are of the form \( \bar{u}_{τ(1)} \ldots \bar{u}_{τ(k)} \), with \( x_1, \ldots, x_k \in Var(ϕ) \) and \( t_1, \ldots, t_k \in \{t, f\} \).

Moreover, for any two distinct tuples there exists i such that one of them is of the form \( \bar{u}_{τ(1)} \ldots \bar{u}_{τ(i)} \ldots \bar{u}_{τ(k)} \) while the other has the form \( \bar{u}_{τ(1)} \ldots \bar{u}_{τ(i)} \ldots \bar{u}_{τ(k)} \). Let v be a valuation; clearly, it cannot be that \( v(\bar{u}^x_0) = v(\bar{u}^x_1) = (0, 1) \), so no two distinct tuples in R both unify with \( (0, 1)^k \). Thus, \#((0, 1)^k, v(R)) ≤ 1.
where the tuples by associating each clause with an identifier in the relation that encodes the formula:

Example 5. Consider the encoding of the 3-CNF formula (2) in Example 4. If \( \ell(C_1) = \alpha \in \text{Const} \), then \( \text{enc}(C_1, \alpha) \) is the following table:

\[
\begin{array}{ccccccc}
\alpha & 0 & 1 & \bot & 0 & 1 & \bot \\
\text{enc}(C_1, \alpha) & 0 & 1 & \bot & 0 & 1 & \bot \\
\end{array}
\]

Our second technical tool is a \((k+1)\)-CNF formula derived from two \(k\)-CNF formulae, to check whether one is satisfiable while the other is not. To this end, for a \(k\)-CNF formula \( \varphi \) and a literal \( \ell \in \{x, \neg x\} \) with \( x \not\in \text{Var}(\varphi) \), we denote by \( \psi \) the \((k+1)\)-CNF formula obtained by adding \( \ell \) to each clause of \( \varphi \). Moreover, for a (finite) set \( \Sigma \) of propositional variables, we let \( \psi(\Sigma) \) denote the \(|\Sigma|\)-CNF formula consisting of all maxterms over \( \Sigma \), except \( \varphi \). Observe that \( \psi(\Sigma) \) has size \( 2^{|\Sigma|} - 1 \), and it is satisfied only by the truth assignment that maps all of the variables in \( \Sigma \) to \( \bot \).

Then, given two \(k\)-CNF formulae \( f \) and \( g \), we define the \((k+1)\)-CNF formula

\[
h(f, g) = f^* \land g^* \land \varphi(f(z_1, \ldots, z_{k+1}))
\]

\[
\land \{x \lor z_2 \lor \cdots \lor z_{k+1}\}
\]

where none of the variables \(x, y, z_1, \ldots, z_{k+1}\) appears in \(\varphi(f) \cup \text{Var}(g)\). This formula has the following property:

Lemma 7. Let \( f \) and \( g \) be \(k\)-CNF formulae. Then, \( f \) is satisfiable and \( g \) is unsatisfiable if and only if the maximum number of clauses of \( h(f, g) \) that can be satisfied by a single truth assignment is exactly \(|h(f, g)| - 1\).

Proof. We denote by \( ||\varphi|| \) the maximum number of clauses that can be satisfied by a single truth assignment, while \( ||\varphi|| \) denotes the number of clauses in \( \varphi \). To avoid the clutter, we let \( \psi \) refer to \( \psi(f(z_1, \ldots, z_{k+1})) \) in (5), and \( h \) refer to \( h(f, g) \); itself, note that \( ||h|| = ||f|| + 2 \cdot ||g|| + 2^{k+1} + 1 \).

\*\*If\*\*

Assume that \( ||h|| = ||h|| - 1 \). We will prove that \( f \) is satisfiable while \( g \) is unsatisfiable by showing that all other possible combinations lead to a contradiction.

Let us start by supposing that there exists a satisfying truth assignment \( \tau \) for \( g \). Then, the extension of \( \tau \) that assigns \( t \) to all the variables in \( \text{Var}(f) \cup \{x, y\} \) and \( t \) to those in \( \text{Var}(\varphi) \) satisfies \( h \), in contradiction of the initial assumption.

We now consider the case when both \( f \) and \( g \) are unsatisfiable. To examine \( ||h|| \), let \( h_1 \) denote \( f^* \land g^* \land \varphi \), and \( h_2 \) consist of all clauses of \( h \) that are not in \( h_1 \), so that \( h = h_1 \lor h_2 \). Note that \( ||h_1|| \leq ||h_1|| + ||h_2|| \); moreover, \( h_2 \) depends on the variables in \( \text{Var}(\varphi) \) while \( h_1 \) does not. We denote \( ||h_2|| \) by \( M \) when all the variables in \( \text{Var}(\varphi) \) are mapped to \( t \), and by \( N \) otherwise. Then, we examine \( ||h_1||, M \), and \( N \) for each of the four possible truth assignments for \( x \) and \( y \):

\[
\begin{array}{cccc}
\text{Assignment} & ||h_1|| & M & N \\
\hline
x \mapsto f & y \mapsto f & f = ||f|| + ||g|| + ||\varphi|| & = ||\varphi|| + 1 < ||\varphi|| + 2 \\
\hline
x \mapsto f & y \mapsto t & f = ||f|| + ||g|| + ||\varphi|| & = ||\varphi|| + 1 < ||\varphi|| + 2 \\
\hline
x \mapsto t & y \mapsto f & f = ||f|| + ||g|| + ||\varphi|| & = ||\varphi|| + 2 < ||\varphi|| + 2 \\
\hline
x \mapsto t & y \mapsto t & f = ||f|| + ||g|| + ||\varphi|| & = ||\varphi|| + 2 < ||\varphi|| + 2 \\
\end{array}
\]

As \( f \) and \( g \) are unsatisfiable, \( ||f|| < ||f|| \) and \( ||g|| < ||g|| \). Therefore, in all the above cases, both \( ||h_1|| + M \) and \( ||h_1|| + N \) are strictly less than \( ||f|| + 2 \cdot ||g|| + ||\varphi|| + 1 \), and so \( ||h|| < ||h|| - 1 \), in contradiction of the initial assumption.

\*\*Only\*\*

Let \( \tau \) be a satisfying assignment for \( f \), and assume that \( g \) is unsatisfiable. The extension of \( \tau \) that maps all variables in \( \text{Var}(g) \cup \{x, y\} \cup \text{Var}(\varphi) \) to \( t \) clearly satisfies all clauses of \( h \) but one, namely \( (x \lor z_2 \lor \cdots \lor z_{k+1}) \). Now, suppose there exists a truth assignment \( \tau \) satisfying all the clauses of \( h \). Then, \( \tau \) satisfies \( g^* \) and, since \( g \) is unsatisfiable, \( \tau(\varphi) = f \). Moreover, \( \tau \) also satisfies \( \varphi \) and thus \( \tau(z_2) = f \) for every \( i \in \{1, \ldots, k+1\} \). In turn, to make the clause \( (\neg x \lor \neg z_2 \lor \cdots \lor \neg z_{k+1}) \) true, we must have \( \tau(x) = f \). Therefore, the clause \( (x \lor z_2 \lor \cdots \lor z_{k+1}) \) of \( h \) is not satisfied by \( \tau \), which is a contradiction. □
The following result is a critical lemma that will allow us to show the hardness of min problems by exhibiting a polynomial-time procedure that constructs a database for every CNF formula (based on the encodings given above), and query with specific properties.

**Lemma 8.** Let \( q \) be an RA query of arity \( 0 \). Let \( dbenc \) be a procedure that for each \( k \)-CNF formula \( \phi \) builds, in polynomial time w.r.t. the size of \( \phi \), a database \( D_\phi \) such that the following properties hold:

1. There exists a polynomially computable number \( \chi \), dependent only on \( k \) and \( |\phi| \), for which: there is a truth assignment that satisfies exactly \( m \) clauses of \( \phi \) if and only if there is a valuation \( v \) with range in \([0,1]\) such that \( \#((),q,v(D_\phi)) = \chi - m \).
2. For every valuation \( v \), there exists a valuation \( v' \) with range in \([0,1]\) such that \( \#((),q,v(D_\phi)) \geq \#((),q,v'(D_\phi)) \).

Then, (a) \( \text{MIN}^+[q] \) is NP-hard, (b) \( \text{MIN}^0[q] \) is coNP-hard, and (c) \( \text{MIN}^-[q] \) is DP-hard.

**Proof.** Observe that (P2) directly implies the following: 

\[
\text{(P3) min}((),q,D_\phi) = \min \{ \#((),q,v(D_\phi)) \mid v \text{ is a valuation with range in } [0,1] \}. 
\]

(a) Let \( k \geq 3 \). We show that \( dbenc \) provides a reduction from \( k\text{-SAT to } \text{MIN}^0[q] \). To this end, let \( \phi \) be a \( k \)-CNF formula, and let \( D_\phi = dbenc(\phi) \).

By (P3), \( \min((),q,D_\phi) = \chi - |\phi| \) if there exists a valuation \( v \) with range in \([0,1]\) such that \( \#((),q,v(D_\phi)) = \chi - |\phi| \). In turn, by (P1), this is the case iff there is a truth assignment satisfying \( \phi \) clauses of \( \phi \). Therefore, \( \phi \) is satisfiable iff \( D_\phi \) has a valuation \( v \) and \( \chi - |\phi| \) is a positive instance of \( \text{MIN}^0[q] \).

(b) Since \( \text{MIN}^+[q] \) is the complement of \( \text{MIN}^0[q] \), its complexity follows directly from the previous point.

(c) We show that \( dbenc \) and (5) together give a reduction from \( \text{SAT-UNSAT to } \text{MIN}^{-}[q] \). To this end, let \( f \) and \( g \) be two \( k \)-CNF formulae with \( k \geq 3 \), let \( \phi \) denote the formula \( h(f, g) \) defined as in (5), and let \( D_{\phi} = dbenc(\phi) \).

By Lemma 7, \( f \) is satisfiable and \( g \) is unsatisfiable iff the maximum number of clauses of \( \phi \) that can be satisfied by the same truth assignment is exactly \( |\phi| - 1 \), which is the case iff \( f \) is unsatisfiable and there is a truth assignment that satisfies \( |\phi| - 1 \) clauses of \( \phi \). In turn, by (P1), this is the case iff both of the following hold:

- there is no valuation \( v' \) with range in \([0,1]\) such that \( \#((),q,v'(D_{\phi})) = \chi - |\phi| \), and
- there exists a valuation \( v \) with range in \([0,1]\) for which \( \#((),q,v(D_{\phi})) = \chi - (|\phi| - 1) = \chi - |\phi| + 1 \).

By (P3), the above hold (together) iff \( \min((),q,D_{\phi}) = \chi - |\phi| + 1 \). Therefore, \( f \) is satisfiable and \( g \) is unsatisfiable if and only if \( D_{\phi} \) has a valuation \( v \) and \( \chi - |\phi| + 1 \) form a positive instance of \( \text{MIN}^{-}[q] \). □

5.3. Computing min: intractability beyond \( RA^+[\cap] \)

While computing min is hard in the general case, there exists a large fragment of RA for which min can be computed via naive evaluation. In the set case this fragment is well known to be positive relational algebra [17] consisting of selection, projection, Cartesian product, and union. Notice that over sets the intersection of two relations is expressible by join, but over bags this is no longer the case. It turns out that good behavior of join with respect to certain answers extends to bags, when we add intersection explicitly. Indeed, for \( RA^+[\cap] \), one can compute min simply by using naive evaluation.

**Theorem 1.** Let \( q \) be an RA expression of arity \( n \), let \( D \) be a database, and let \( \bar{a} \in Const(D)^n \). Then, \( \min(\bar{a}, q, D) = \text{naive}(\bar{a}, q, D) \).

**Proof.** This is an immediate consequence of a more general result that we shall see later on (Proposition 9). □

From the fact that bag relational algebra queries are in DLocSpace with respect to data complexity [5,6], we then immediately get the following:

**Corollary 5.** For expressions \( q \) in \( RA^+[\cap] \), the problems \( \text{MIN}^0[q] \), \( \text{MIN}^-[q] \) and \( \text{MIN}^+[q] \) are all in DLocSpace. □

As a matter of fact, \( RA^+[\cap] \) is the best fragment for which we can compute certain answers efficiently under bag semantics. To show this, from the diagram in Fig. 1, it suffices to prove that the problem is intractable for \( \text{SPC}[\cup] \), as well as for all fragments with duplicate elimination. This is what we do next; in particular, we shall see that in all of these fragments the intractable complexity is exactly the same, namely NP-complete, coNP-complete, and DP-complete, when \( \theta = <, >, = \), respectively.

**Hardness for \( SPC[\cup] \).** We first study the max-union operator \( \cup \). Recall that, in the set case, adding union is harmless and preserves the property that certain answers can be found by naive evaluation. But under bag semantics, adding \( \cup \) to SPC gives rise to a substantial increase in the complexity of computing min.

**Theorem 2.** There exists an SPC[\cup] query \( q \) for which \( \text{MIN}^0[q] \) is NP-hard, \( \text{MIN}^-[q] \) is coNP-hard, and \( \text{MIN}^+[q] \) is DP-hard.

**Proof.** Let \( \phi \) be a \( k \)-CNF formula, and define \( dbenc(\phi) \) as the database with relations \( R \) and \( T \), where \( R \) is the encoding of \( \phi \), and \( T \) consists of precisely \( |\phi| \) occurrences of \((0,1)^2 \). Consider the query \( q = \pi_T(R \cup T) \); we shall show that \( dbenc \) and \( q \) satisfy the properties of Lemma 8.

Let \( v \) be a valuation, let \( A = \text{adom}(v(D_\phi)) \), and let \( \bar{u} = (0,1)^2 \). First, we will show that

\[
\#((),q,v(D_\phi)) = 2^k \cdot |\phi| \geq (2^k - 1) \cdot |\phi| 
\]

By definition of projection, \( \#((),\pi_T(R \cup T), v(D_\phi)) \) is equal to

\[
\sum_{\bar{a} \in A} \sum_{\bar{v} \in v(R)} \#(\bar{a}, R \cup T, v(D_\phi)) 
\]

As \( R = R_\phi \) and \( T \) does not contain any tuple distinct from \( \bar{u} \), \( (1) \) equals

\[
\sum_{\bar{a} \in A \setminus \bar{u}} \#(\bar{a}, v(R)) + \#(\bar{u}, R \cup T, v(D_\phi)) 
\]

The summation above amounts to \((|v(R)|) - \#(\bar{u}, v(R))\), and by definition of \( \cup \) we have that \((1) \) is equal to max \((\bar{u}, v(R) \cup (\bar{u}, v(T))) \). By construction, \( T \) consists of exactly \(|\phi| \) occurrences of the constant tuple \( \bar{u} \), so \#(\bar{u}, v(T)) = |\bar{u}, v(T)| = |v(T)|. In turn, since \(|v(R)| = |v(R)| = (2^k - 1) \cdot |\phi| \), we have that \((2) \) is equal to

\[
(2^k - 1) \cdot |\phi| \geq \max \#(\bar{u}, v(R)) |\phi| 
\]

Obviously \( \#(\bar{u}, v(R_\emptyset)) \leq |\varphi| \) by Lemma 6, so \((\dagger)\) \(\Rightarrow |\varphi|\). Thus, from (6.3) we directly get (6).

By Lemma 6, there exists a truth assignment that satisfies \( m \) clauses of \( \varphi \) iff there exists a valuation \( v \) with range in \([0, 1]\) such that \( \#(\bar{u}, v(R_\emptyset)) = m \). In turn, from (6), this is the case iff \( \#((q), v(D_{\emptyset})) = 2^k \cdot |\varphi| - m \), thus proving that (P1) holds for \( \chi = 2^k \cdot |\varphi| \). In addition, from (6) and Lemma 6(d) it directly follows that (P2) holds as well. □

Handling duplicate elimination. In terms of tractability, no fragment survives the addition of duplicate elimination. Indeed, for all fragments from SPC[\( \epsilon \)] to full relational algebra RA, the decision problems are NP-complete, coNP-complete, and DP-complete for \(<, \geq \) and \(=\), respectively.

Theorem 3. There exists an SPC[\( \epsilon \)] query \( q \) for which MIN\(^{-}[q]\) is NP-hard, MIN\(^{-}[q]\) is coNP-hard, and MIN\(^{-}[q]\) is DP-hard.

Proof. Let \( \varphi \) be a k-CNF formula, define \( db\text{enc}(\varphi) \) as the database \( D_\varphi \) consisting of the relation \( S = \text{enc}(\varphi, i) \), for some injection \( i \) from \( \varphi \) to Const, and consider the query \( q = \pi_j(\text{enc}(\varphi)) \).\(^3\) We will show that \( db\text{enc} \) and \( q \) satisfy the properties of Lemma 8.

By construction and by Lemma 6(a), for every valuation \( v \), the number of occurrences of \( \iota(C)(0, 1)^k \) in \( \text{enc}(\varphi, i) \) is either 1 or 2, and any other tuple occurs at most once. Recall also that, for distinct clauses \( C \) and \( C' \), no tuple in \( \text{enc}(\varphi, i) \) unifies with any tuple in \( \text{enc}(\varphi, i') \).

From Lemma 6(c) it follows that (P1) holds for \( \chi = 2^k \cdot |\varphi| \) if we show that, for every valuation \( v \),

\[
\#((q), v(D_\varphi)) = 2^k \cdot |\varphi| - m \iff \#((0, 1)^k, v(R_\emptyset)) = m, \tag{7}
\]

where \( R_\emptyset = \text{enc}(\varphi) \). In addition, from (7) and Lemma 6(d) it also follows that (P2) holds.

Let \( v \) be a valuation, and let \( S_j \) denote the set of tuples that occur precisely \( j \) times in \( v(S) \). Then,

\[
\#((q), v(D_\varphi)) = \sum_{a \in S_1} 1 + \sum_{a \in S_2} 1 = |v(S)| - \sum_{a \in S_2} 1.
\]

Since \( |v(S)| = |S| = 2^k \cdot |\varphi| \), we have that \( \#((q), v(D_\varphi)) = 2^k \cdot |\varphi| - m \) if and only if \( \sum_{a \in S_2} 1 = m \). In turn, this is the case iff

\[
(\dagger) \text{ there exist exactly } m \text{ distinct clauses } C_1, \ldots, C_m \text{ in } \varphi \text{ such that, for every } i \in \{1, \ldots, m\}, \#(\iota(C_i)(0, 1)^k, v(\text{enc}(\varphi, i))) \text{ is equal to } 2.
\]

By construction, we have that \( \#(\iota(C)(0, 1)^k, v(\text{enc}(\varphi, i))) = 2 \) iff \( \#((0, 1)^k, v(\text{enc}(C))) = 1 \), for every \( C \in \varphi \). So, by Lemma 6(a), (\dagger) holds iff \( \#((0, 1)^k, v(R_\emptyset)) = m \). □

5.4. Computing max: hardness for simple queries

The problem of computing max is hard already for very simple queries: in fact, MAX\(^{-}[q]\) is NP-complete for a query \( q \) that returns a base relation \([21]\). Here, we complete the picture by proving that deciding MAX\(^{-}[q]\) for the same class of queries is complete for DP.

Theorem 4. The problem MAX\(^{-}[q]\) is DP-hard even for a query \( q \) that returns a base relation.

Proof. We provide a reduction from SAT-UNSAT. To this end, let \( f \) and \( g \) be two 3-CNF formulae, let \( \varphi \) denote \( h(f, g) \), let \( D_\varphi \) be the database consisting of the single relation \( R = R_\varphi \), and consider the query \( q = R \). Observe that \( \varphi \) is a 4-CNF formula and, for every valuation \( v \), we have that \( \#((0, 1)^k, q, v(D_\varphi)) = \#((0, 1)^k, v(R_\varphi)) \).

By Lemma 7, \( f \) is satisfiable and \( g \) is unsatisfiable iff the maximum number of clauses of \( \varphi \) that can be satisfied by a single truth assignment is \(|\varphi| - 1 \). By Lemma 6(c), this is the case iff both of the following hold:

(1) there exists a valuation \( v \) with range in \([0, 1]\) such that \( \#((0, 1)^k, v(R_\varphi)) = |\varphi| - 1 \), and

(2) there is no valuation \( v' \) with range in \([0, 1]\) such that \( \#((0, 1)^k, v(R_\varphi)) = |\varphi| \).

Observe that Lemma 6(d) directly implies that

\[
\max_{v \in V} \#((0, 1)^k, v(R_\varphi)) = \max_{v \in V} \#((0, 1)^k, v(R_\varphi)).
\]

where \( V \) is the set of all valuations, and \( V' \subseteq V \) consists of all valuations with range in \([0, 1]\).

Thus, (1) and (2) hold together iff \( \max_{v \in V} \#((0, 1)^k, q, D_\varphi) = |\varphi| - 1 \). Therefore, \( f \) is satisfiable and \( g \) is unsatisfiable iff \( D_\varphi, (0, 1)^k \), and \(|\varphi| - 1 \) are a positive instance of MAX\(^{-}[q]\) for \( q = R \). □

5.5. Complex selection conditions

In our definition of relational algebra, we assumed that selection conditions are equalities of the form \( i = j \), where \( i \) and \( j \) denote positions within a table. Selection conditions can be generalized to arbitrary Boolean combinations of equalities, according to the following grammar:

\[
\gamma := (i = j) \mid \gamma \land \gamma \mid \gamma \lor \gamma \mid \neg \gamma.
\]

We briefly describe how more complex conditions affect our results.

If we only add conjunction (that is, selection conditions are conjunctions of equalities), there is no change at all. This is because the cascade-of-selections equivalence,

\[
\sigma_{\gamma \land \gamma'}(e) = \sigma_\gamma(\sigma_{\gamma'}(e)),
\]

applies under bag semantics as well.

If we add disjunction, it might at first appear that this leads to intractability, because the following equivalence

\[
\sigma_{\gamma \lor \gamma'}(e) = \sigma_\gamma(e) \cup \sigma_{\gamma'}(e)
\]

holds under bag semantics, and we have seen that the fragment SPC[\( \cup \)] is intractable. However, adding disjunction to selection conditions is weaker than adding max-union, and preserves tractability.

Proposition 9. Let \( q \) be an RA\(^+\)[\( \cap \)] query of arity \( n \), where selection conditions are positive Boolean combinations of equalities; then, MIN\(^{-}[q]\) and MIN\(^{-}[q]\) can be solved in DLogSpace. More precisely, for every database \( D \) and for every \( n \)-tuple \( \bar{a} \) of constants, min\((\bar{a}, q, D) = \text{naive}(\bar{a}, q, D)\).

Proof. For every valuation \( v \), we have \( v(\bar{a}) = \bar{a} \) and

\[
\text{naive}(\bar{a}, q, D) \leq \sum_{\bar{d}: \bar{d} \notin \bar{a}} \text{naive}(\bar{a}, q, D) \leq \#(\bar{a}, q, v(D)).
\]

where the rightmost inequality is by Lemma 9, which is given in Appendix. Let us now define a valuation \( v \) whose restriction to Null(\( D \)) is injective and such that the image of Null(\( D \)) under it is disjoint with Const(\( D \)). In other words, each null in \( D \) is mapped to a distinct constant that does not appear in \( D \).

From the definition of naive evaluation, it then follows that

\[
\#(\bar{a}, q, v(D)) = \text{naive}(\bar{a}, q, D),
\]

This, together with (8), proves that

\[
\text{naive}(\bar{a}, q, D) = \min(\bar{a}, q, D).
\]

\(^3\) The output of this query is always either the empty bag, or the bag consisting of a single occurrence of the empty tuple ().
The problems become intractable when conditions are unrestricted Boolean combinations of equalities, even when these are added to the SPC fragment.

**Proposition 10.** In the extension of SPC that allows arbitrary Boolean combinations of equalities as selection conditions, there is a query \( q \) for which \( \text{MIN}^-[q] \) is NP-complete, \( \text{MIN}^+[q] \) is coNP-complete, and \( \text{MIN}^0[q] \) is DP-complete.

**Proof.** Let \( \varphi \) be a \( k \)-CNF formula, and define \( \text{dbnec}(\varphi) \) as the database \( D_\varphi \) with relations \( R \) and \( T \), where \( R \) is the encoding of \( \varphi \) and \( T \) consists of a single occurrence of \((0,1)^k\). Consider the query \( q = \pi_{\alpha}(R \times T) \), where \( \gamma \) is the disjunction of all inequalities \( i \neq j \) for every \( i \in \{1, \ldots, 2^k\} \) and \( j = 2^k + 1 \). We will show that \( \text{dbnec} \) and \( q \) satisfy the properties of Lemma 8.

For a valuation \( v \), the answer the to \( q \) on \( v(D_\varphi) \) consists of as many occurrences of \( (\cdot) \) as there are tuples different from \((0,1)^k \) in \( R_\varphi \).

More precisely,

\[
\#(\cdot, q, v(D_\varphi)) = \sum_{\tilde{a} \neq (0,1)^k} \#(\tilde{a}, v(R_\varphi))
\]

\[
= |v(R_\varphi)| - \#((0,1)^k, v(R_\varphi)).
\]

Therefore, \((P1)\) holds for \( \chi = (2^k - 1) \cdot |\varphi| = |R_\varphi| = |v(R_\varphi)| \) by Lemma 6(c). In addition, from \((9)\) and Lemma 6(d) it also follows that \((P2)\) holds. \( \square \)

6. Conclusions

We have provided two complete classifications: of the expressive power of fragments of bag relational algebra, and of the complexity of computing certain and possible answers in those fragments. For the complexity of certain answers, we have a dichotomy: either they can be computed efficiently by naive evaluation, or their complexity is intractable, which means NP-complete, or coNP-complete, or DP-complete (depending on how the problem is turned into a decision problem).

Directions for future work are motivated by the recent work on bag semantics in data management applications where incompleteness naturally occurs, such as data exchange [15] and OBDA [16]. Notice that we have primarily concentrated on the closed-world semantics, which as of late has been actively studied in those contexts; see, e.g., [27–31]. Thus we believe our results could be relevant to understanding the complexity of these applications under the open-world assumption. As another direction for future work, we would like to study the complexity of finding certain and possible answers in the fragments of bag relational algebra under the open-world assumption. The general case is of course undecidable, but the picture for the fragments studied here is not clear. Finally, we would like to use our results as the starting point for the study of answering queries with grouping and aggregation over incomplete data, as such queries rely on bag semantics.

Appendix. Additional proofs

**Proof of Lemma 3.** We proceed by induction on the structure of \( e \). Note that all subexpressions of \( e \) are nullary and, since there are no attributes, none of them can be a selection. Moreover, according to the syntax of bag relational algebra defined in Section 2, every subexpression of \( e \) must mention \( R \) at least once (and it does not mention any other symbol of the schema due to the assumptions of the lemma).

**Base case:** \( e = R \). Then, \(|e(D)| = |R_0| \).

**Inductive step:**

- \( e = \pi_{\alpha}(e') \). Then, \(|e(D)| = |e'(D)| \) and by the induction hypothesis \(|e'(D)| \geq |R'|\).
- \( e = e' + e'' \). Then, \(|e(D)| = |e'(D)| \cdot |e''(D)| \). By the induction hypothesis \(|e'(D)| \) and \(|e''(D)| \) are both \( \geq |R'| \), and thus their product is as well.
- \( e = e' \cup e'' \). Then, \(|e(D)| = \max\{|e'(D)|, |e''(D)|\} \geq |e'(D)| \) and by the induction hypothesis \(|e'(D)| \geq |R'| \).
- \( e = e' \times e'' \). Then, \(|e(D)| = |e'(D)| + |e''(D)| \geq |e'(D)| \). By the induction hypothesis both \(|e'(D)| \) and \(|e''(D)| \) are \( \geq |R'| \), and therefore their sum is as well. \( \square \)

**Proof of Lemma 4.** We proceed by induction on the structure of \( e \). Note that all subexpressions of \( e \) are nullary and, since there are no attributes, none of them can be a selection.

**Base case:** \( e = e_k \times e_s \), where \( \star \in \{\times, \div, \cup\} \) and \( e_k, e_s \) are \( RA^+ \cup \{\} \) expressions such that \( e_k \) mentions only \( R \) and \( e_s \) mentions only \( S \). Then, we have \(|e(D)| = f_{\star}(|e_k(D)|, |e_s(D)|) \). By the induction hypothesis \(|e_k(D)| \) and \(|e_s(D)| \) are \( \geq |R| \), and therefore their product is as well.

**Inductive step:** Straightforward application of the induction hypothesis as in Lemma 3. \( \square \)

**Lemma 9.** Let \( q \) be a \( n \)-ary expression in \( RA^+ \{\cap\} \) and let \( D \) be a bag semantics database. For every tuple \( \bar{a} \in \text{adom}(D) \) and every valuation \( v \) for \( \text{Nul}(D) \) the following inequality holds:

\[
\sum_{\{\bar{b} \in \text{adom}(D) \mid v(\bar{b}) = \bar{a}\}} \text{naive}(\bar{b}, q, D) \leq \sum_{\{\bar{e} \in \text{adom}(D) \mid v(\bar{e}) = \bar{e}\}} \text{naive}(\bar{e}, q, D)
\]

**Proof.** We proceed by induction on the structure of \( q \).

**Base case:** \( q = R \). Trivially, each occurrence of \( \bar{a} \in R_0 \) results in one occurrence of \( v(\bar{a}) \) in \( R(D) \).

**Inductive step:**

- \( q = \pi_{\alpha}(q') \). Assume that \( q' \) has arity \( m \). Due to the definition of Projection, the following equality holds for every valuation \( v \) for \( \text{Nul}(D) \):

\[
\#(v(\bar{a}, \pi_{\alpha}(q')), vD) = \sum_{\{\bar{e} \in \text{adom}(D) \mid v(\bar{e}) = \bar{e}\}} \#(\bar{e}, q', vD).
\]

Notice that \( \bar{e} \) in Eq. (A.1) is a tuple of constants, hence from the definition of semantics for incomplete databases we can conclude that there exists at least one tuple \( \bar{u} \in \text{adom}(D) \) such that \( v(\bar{u}) = \bar{e} \). We now apply the inductive hypothesis
to $q'$ and $\bar{u}$ and derive the following:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=\bar{u}} \text{naive}(\bar{b}, q', D) \leq \#(v\bar{u}, q', vD). \tag{A.2}
\]
By assumption, $v\bar{u}$ in Eq. (A.2) is equal to $\bar{c}$. For this reason, we can substitute $v\bar{u}$ with $\bar{c}$ obtaining the following inequality:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=\bar{u}} \text{naive}(\bar{b}, q', D) \leq \#(\bar{c}, q', vD). \tag{A.3}
\]
Observe now that $v$ is a function, hence for every $\bar{b} \in \text{dom}^m(D)$ there exists one and only one tuple $\bar{c}$ of constants such that $v\bar{b} = \bar{c}$. In light of this consideration, we can apply Eq. (A.3) to each tuple $\bar{c}$ in the right-hand side of Eq. (A.1) and obtain the following inequality:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=\bar{u}} \left( \sum_{\bar{c} \in \text{dom}^m(D) \mid \bar{c} = v\bar{b}} \text{naive}(\bar{b}, q', D) \right) \leq \sum_{\bar{c} \in \text{dom}^m(D) \mid \bar{c} = v\bar{u}} \#(\bar{c}, q', vD). \tag{A.4}
\]
The double summation on the left-hand side of Eq. (A.4) can now be re-written as a single summation over all those tuples $\bar{b}$ such that $v\bar{b}$ is equal to $v\bar{a}$ on $\alpha$. Hence:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q', D) \leq \sum_{\bar{c} \in \text{dom}^m(D) \mid \bar{c} = v\bar{u}} \#(\bar{c}, q', vD). \tag{A.5}
\]
Consider now naive($\bar{a}$, $\pi_a(q')$, $D$), and let $\bar{z}$ be a generic tuple in $\text{dom}^m(D)$ such that $\bar{z}$ is equal to $\bar{a}$ on the attributes in $\alpha$. Since
\[
Z = \{ \bar{z} \in \text{dom}^m(D) \mid \bar{z} \text{ is equal to } \bar{a} \text{ on } \alpha \}
\]
is a subset of
\[
B = \{ \bar{b} \in \text{dom}^m(D) \mid v\bar{b} \text{ is equal to } v\bar{a} \text{ on } \alpha \},
\]
the following inequality holds:
\[
\sum_{\bar{z} \in Z} \text{naive}(\bar{z}, q', D) \leq \sum_{\bar{b} \in B} \text{naive}(\bar{b}, q', D).
\]
The claim now follows from the definition of projection, that is,
\[
\text{naive}(\bar{a}, \pi_a(q'), D) = \sum_{\bar{z} \in Z} \text{naive}(\bar{z}, q', D).
\]
• $q = \sigma_{\gamma}(q')$, where $\gamma$ is a positive Boolean combination of equalities. W.l.o.g. we assume $\gamma$ to be in disjunctive normal form, that is, $\gamma = \bigvee_i(\bigwedge_{j < i} b_{ij} = b_{ij})$.
If this is the case, a tuple $\bar{a}$ satisfies $\gamma$ if it satisfies all the equalities in one of the disjuncts of $\gamma$.
Let $A$ be the set of $n$-tuples that unify with $\bar{a}$; for every valuation $v$ we have
\[
\sum_{\bar{z} \in A} \text{naive}(\bar{z}, \sigma_{\gamma}(q'), D) \leq \sum_{\bar{z} \in A} \text{naive}(\bar{z}, q', D) \leq \#(v(\bar{a}), q', v(D)), \tag{A.6}
\]
where the left inequality is by definition of the selection operation, and the right one is by the inductive hypothesis.
If $v(\bar{a})$ satisfies $\gamma$, then
\[
\#(v(\bar{a}), \sigma_{\gamma}(q'), v(D)) = \#(v(\bar{a}), q', v(D))
\]
and so the claim follows by Eq. (A.6). Otherwise, when $v(\bar{a})$ does not satisfy $\gamma$, for each disjunct of $\gamma$ there is an equality $i = j$ not satisfied by $v(\bar{a})$. Then, from the definition of selection we have $\#(v(\bar{a}), \sigma_{\gamma}(q'), v(D)) = 0$.
Observe now that equalities are functions, hence $v\bar{a}, i \neq v\bar{a}, j$ implies that $\bar{a}, i \neq \bar{a}, j$. In turn, this implies all the tuples $\bar{b} \in \text{dom}^m(D)$ such that $v\bar{b} = v\bar{a}$ do not satisfy the equality conditions violated by $v\bar{a}$. From this consideration, we can conclude that $\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b} = v\bar{a}} \text{naive}(\bar{b}, \sigma_{\gamma}(q'), D) = 0$, proving the claim.
• $q = q_1 \lor q_2$. From the definition of $\lor$ we have the following:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_1 \lor q_2, D) = \sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_1, D) + \sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_2, D). \tag{A.7}
\]
Applying the inductive hypothesis to $q_1$ and $q_2$ we obtain:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_1, D) \leq \#(v\bar{a}, q_1, vD); \tag{A.8}
\]
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_2, D) \leq \#(v\bar{a}, q_2, vD). \tag{A.9}
\]
Finally, we apply the definition of additive union to $vD$ and obtain the following:
\[
\#(v\bar{a}, q_1 \lor q_2, vD) = \#(v\bar{a}, q_1, vD) + \#(v\bar{a}, q_2, vD). \tag{A.10}
\]
The claim now follows from Eqs. (A.7), (A.8), (A.9), (A.10).

• $q = q_1 \times q_2$. Suppose that the arity of $q_1$ is $a$ and the arity of $q_2$ is $b$, and assume two tuples $\bar{a}_1 \in \text{dom}^m(D)$ and $\bar{a}_2 \in \text{dom}^m(D)$ such that $\bar{a} = \bar{a}_1 \circ \bar{a}_2$. From the definition of Cartesian product we obtain the following.
\[
\#(v\bar{a}, q_1 \times q_2, vD) = \#(v\bar{a}, q_1, vD) \cdot \#(v\bar{a}_2, q_2, vD). \tag{A.11}
\]
Applying the inductive hypothesis on $v\bar{a}_1$ and $v\bar{a}_2$, we obtain the following inequalities:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}_1} \text{naive}(\bar{b}, q_1, D) \leq \#(v\bar{a}_1, q_1, vD); \tag{A.12}
\]
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}_2} \text{naive}(\bar{b}, q_2, D) \leq \#(v\bar{a}_2, q_2, vD). \tag{A.13}
\]
We now apply Eqs. (A.12) and (A.13) to Eq. (A.11), and we derive the following:
\[
\sum_{\bar{b} \in \text{dom}^m(D) \mid v\bar{b}=v\bar{a}} \text{naive}(\bar{b}, q_1 \times q_2, D) \leq \#(v\bar{a}, q_1 \times q_2, vD). \tag{A.14}
\]
Let $S = \{ \bar{b} \in \text{dom}^m(D) \mid v\bar{b} = v\bar{a}\}$. From the definition of Cartesian product we can derive the following equality:
\[
\sum_{\bar{b} \in S} \text{naive}(\bar{b}, q_1 \times q_2, D) = \sum_{\bar{b}_1, \bar{b}_2 \in \text{dom}^m(D) \mid q_1 = \bar{b}_1 \times \bar{b}_2} \text{naive}(\bar{b}_1, q_1, D) \cdot \text{naive}(\bar{b}_2, q_2, D). \tag{A.15}
\]
To prove the claim, observe that the left-hand side of Eq. (A.14) is always greater or equal to the right-hand side of Eq. (A.15).

- $q = q_1 \cap q_2$. From the definition of $\cap$ we can derive the following:

$$
\sum_{(\text{biconcat}(\bar{b}, q_1 \cap q_2, D) \in \text{vD})} \text{naive}(\bar{b}, q_1 \cap q_2, D) = \\
\sum_{(\text{biconcat}(\bar{b}, q_1, D) \in \text{vD})} \min\{\text{naive}(\bar{b}, q_1, D), \text{naive}(\bar{b}, q_2, D)\}.
$$

(A.16)

We now apply the inductive hypothesis to $q_1$ and $q_2$ and obtain the following:

$$
\sum_{(\text{biconcat}(\bar{b}, q_1, D) \in \text{vD})} \text{naive}(\bar{b}, q_1, D) \leq \#(\text{v\bar{a}}, q_1, \text{vD});
$$

(A.17)

$$
\sum_{(\text{biconcat}(\bar{b}, q_2, D) \in \text{vD})} \text{naive}(\bar{b}, q_2, D) \leq \#(\text{v\bar{a}}, q_2, \text{vD}).
$$

(A.18)

Finally, we apply the definition of intersection to $\text{vD}$ and obtain the following.

$$
\#(\text{v\bar{a}}, q_1 \cap q_2, \text{vD}) = \min\{\#(\text{v\bar{a}}, q_1, \text{vD}), \#(\text{v\bar{a}}, q_2, \text{vD})\}.
$$

(A.19)

We now observe that the right-hand side of Eq. (A.16) is always lesser or equal to the left-hand side of Eqs. (A.17) and (A.18). This is due to the application of the $\min$ operator. In turn, together with Eq. (A.19) this proves that the following inequality holds:

$$
\sum_{(\text{biconcat}(\bar{b}, q_1 \cap q_2, D) \in \text{vD})} \text{naive}(\bar{b}, q_1 \cap q_2, D) \leq \#(\text{v\bar{a}}, q_1 \cap q_2, \text{vD}).
$$

This in turn proves the claim. □
