L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Abstract—In this paper we propose a visual servoing approach that controls the deformation of a suspended tether cable subject to gravity from visual data provided by a RGB-D camera. The cable shape is modelled with a parabolic curve together with the orientation of the plane containing the tether. The visual features considered are the parabolic coefficients and the yaw angle of that plane. We derive the analytical expression of the interaction matrix that relates the variation of the visual features to the velocities of the cable extremities. Singularities are demonstrated to occur if and only if the cable is taut horizontally or vertically. An image processing algorithm is also developed to extract in real-time the current features fitting the parabola to the cable from the observed point cloud. Simulations and experimental results demonstrate the efficiency of our visual servoing approach to deform the tether cable toward a desired shape configuration.

I. INTRODUCTION

The manipulation of Deformable Linear Objects (DLO) by a robotic manipulator is a challenging task due to the high number of DLO degrees of freedom (DOF) and the low number of robot DOF. Cable routing and cable inserting are common examples of DLO manipulation tasks in industry. Since these tasks are still mainly performed manually, their automation by robots has a great potential [8], [7], [6], [23]. In particular, two robot arms are used in [11] for manipulating a flexible beam in order to adapt its shape before an assembly operation. Accurately and automatically controlling the shape of a suspended cable can also be useful for Unmanned Aerial Vehicle (UAV) applications such as managing the shape of the power cable of tethered UAVs. For instance, [22] proposed a device composed of a winch mounted on the ground that is controlled to maintain the power cable in a slack configuration to avoid pulling the drone or touching the ground. [13] proposed an UAV controller that maintains the cable taut for canceling its oscillation and improving the flight stability. Another possible application is aerial transportation performed by a flying gripper made of two UAVs linked by a cable [5] or by cable-suspended parallel robots actuated by flying robots [4], [15]. Controlling the shape of power cables linking a chain of underwater robots was also considered in [11].

In the following, we present some works concerning the shape control of DLO using visual servoing. They are divided into two families: model-based and model-free approaches. In the model-free branch, the DLO is usually modeled as a set of points [1], [10], [19] or a contour [14] that can be represented by geometrical features. The common way to control the object deformation is by minimizing the error between the current measure of these features and their desired values corresponding to the targeted shape. In [1] the considered features are the 3D positions of markers attached on the DLO while in [10] a set of 3D equidistant points lying on a B-spline curve fitting the shape is considered. In [14] four different cases of features are studied: contour polynomial spline coefficients, Bezier and Nurb spline points, and Fourier coefficients. To relate the variation of these features to the velocities of the robot end-effector that interacts with the DLO, [11] propose to estimate an approximate shape Jacobian matrix during an offline identification procedure that consists in deforming the DLO by applying open-loop step motions on each robot DOF and measuring the induced displacements of the attached markers. The shape Jacobian matrix can also be estimated online from visual data by using a Kalman filter [14] or by minimizing a quadratic objective on a sliding time windows [10]. More recently, [16] proposed a control scheme relying on a shape Jacobian that is updated online from simulations based on a geometrical deformation model [17]. In another way, a neural network is trained in [19] during an offline procedure for predicting the shape Jacobian matrix from the position of the cable control points. All aforementioned works allow to control the shape of the DLO without knowledge of its mechanical properties. However, the limitations of these approaches are the inability to determine possible singular configurations of the system that may cause instabilities in the control and the potential convergence of the system to local minima if the goal configuration is too far away. Moreover, the approaches that require an online estimation of the shape Jacobian are sensitive to measurement noise.

In the model-based branch of methods, a way to control the shape of a soft body consists in using a mechanical model that predicts its behavior. However, depending of its complexity, it may be difficult to run this model in real-time. The authors of [9] consider control points velocities as features and use a Finite Element Model that formulates locally the static equilibrium equations for these points to avoid real-time model simulations. In some cases the control input can be derived directly from model equations as it is done in [5] and [11] with a catenary/chain curve.

In this work, we focus on the robotic manipulation of a suspended tether cable that is subject to gravity in order to control its shape. In that case, the cable can be slack or...
taut and we propose to generalize this possible set of configurations in a single and simple geometrical model: a $2^{nd}$ order polynomial curve, that is, a parabola. We show through simulations and experimental results that such approximation is sufficient. The proposed shape control approach only uses the length of the cable as a priori knowledge and the visual information provided by a RGB-D camera observing the cable. Moreover, it is capable of operating with slack and taut configurations and does not need to observe the cable extremities. In particular, the chain model considered in [11] and in [5] does not allow to consider any taut configurations due to a singularity of the corresponding shape Jacobian, while our parabola model is not singular in this configuration apart when the cable is taut horizontally or vertically. An analytic expression of the shape Jacobian is derived, from which a complete model-free methods mentioned earlier. Another advantage of our solution is that it does not consider any mechanical model of the DLO and thus does not need any knowledge about its material mechanical properties. In contrast, our method relies only on an approximate geometrical model that is extracted and tracked from RGB-D data.

The paper is organized as follows: Section II presents the related Shape Jacobian matrix is analytically derived, from which a complete singular Value Processing developed to track in real-time the cable shape is given by

$$H = aD^2 + bD.$$ Since $H$, $\frac{\partial S}{\partial t}$ and $\frac{\partial S}{\partial w}$ have been defined with parallel z axis, their relative pose is given by the homogeneous transformation matrix ($c$ stands for cos, $s$ for sin):

$$wH = \begin{bmatrix} c\alpha & -s\alpha & 0 & w_p \end{bmatrix} \begin{bmatrix} 0 & c\alpha & 0 & w_p \end{bmatrix} \begin{bmatrix} 0 & 0 & 1 & w_p \end{bmatrix} \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}$$

This allows expressing any tether point in $F_w$ by:

$$w = w_p + \begin{bmatrix} t_x \alpha x^2 + b \end{bmatrix}$$

In particular, the coordinates of point $p_f$ in $F_w$ is given by:

$$w = w + \begin{bmatrix} D \alpha x \alpha aD^2 + bD \end{bmatrix}$$

B. Interaction matrix

As already said, the set $S$ of visual features we consider is:

$$S = \begin{bmatrix} a & b & \alpha \end{bmatrix}$$

We are now interested in determining the time variation of $S$ in function of the time variation of $w_p$ and $w_p$ in $F_w$ for obtaining the analytical form of the interaction matrix of $S$. By differentiating (4) we obtain:

$$w_f = w + \begin{bmatrix} D \alpha x \alpha aD^2 + bD \end{bmatrix}$$

Fig. 1: Tether (green curve) and its parabola model (red curve): $D > 0$, $H < 0$ in this configuration.
This equation can be rewritten as:

\[
\begin{bmatrix}
\dot{w} \\
\dot{\mathbf{f}} \\
\dot{\mathbf{m}}
\end{bmatrix} = 
\begin{bmatrix}
0 & 0 & \cos \alpha \\
0 & 0 & \sin \alpha \\
D^2 & D & 2aD + b
\end{bmatrix}
\begin{bmatrix}
\dot{a} \\
\dot{b} \\
\dot{D}
\end{bmatrix}
\]  
(7)

As \( D \) depends on \( a \) and \( b \), it is necessary to eliminate \( \dot{D} \) from \( \mathbf{f} \) to get a one-to-one relation between \( \dot{s} \) and \( \dot{w} \dot{\mathbf{f}} - \dot{w} \dot{\mathbf{m}} \).

In frame \( \mathcal{F}_L \), \( D \) is related to \( a \) and \( b \) and the tether length \( L \) by the following equation:

\[
L = \int_0^D \sqrt{1 + (2ax + b)^2} \, dx
\]  
(8)

To solve this integral analytically, we choose \( t = 2ax + b \), from which we deduce \( dt = 2adx \) and we obtain:

\[
L = \frac{1}{2a} \int_{t_1}^{t_2} \sqrt{1 + t^2} \, dt
\]  
(9)

where \( t_1 = b \) and \( t_2 = 2aD + b \). Notice that this equation is not valid when \( a = 0 \) (that is, when the parabola degenerates to a straight line, in which case the tether is taut) for which:

\[
L = D \sqrt{1 + b^2} = \sqrt{D^2 + H^2}
\]  
(10)

Since it is well known that:

\[
\int \sqrt{1 + t^2} \, dt = \frac{1}{2} t \sqrt{1 + t^2} + \frac{1}{2} \ln \left| t + \sqrt{1 + t^2} \right|
\]  
(11)

and

\[
\ln \left| t + \sqrt{1 + t^2} \right| = \arcsinh t, \ t \in \mathbb{R}
\]  
(12)

we finally obtain the expression of the tether length:

\[
L = f(D, a, b)
\]  
(13)

\[
= \left( t_2 \sqrt{1 + t_2^2} - b \sqrt{1 + b^2}
\right.
\]  
\[
+ \arcsinh t_2 - \arcsinh b \right) / (4a)
\]

Since \( \dot{L} = 0 \), by differentiating \( \mathbf{f} \) we get:

\[
\frac{\partial \mathbf{f}}{\partial D} \dot{D} = -\frac{\partial \mathbf{f}}{\partial a} \dot{a} - \frac{\partial \mathbf{f}}{\partial b} \dot{b}
\]  
(14)

from which we obtain:

\[
\dot{D} = k_1 \dot{a} + k_2 \dot{b}
\]  
(15)

where

\[
k_1 = 4(L - D \sqrt{1 + t_2^2}) / k
\]  
(16)

\[
k_2 = 2(\sqrt{1 + b^2} - \sqrt{1 + t_2^2}) / k
\]  
(17)

with

\[
k = 4a \sqrt{1 + t_2^2}
\]  
(18)

We can note that \( k = 0 \) when \( a = 0 \) (i.e., the tether is taut). Fortunately, after applying a first order Taylor expansion to the term \( f(a) = \sqrt{1 + t_2^2} = \sqrt{1 + (2Da + b)^2} \), we obtain

\[
\lim_{a \to 0} k_1 = \frac{-2D^2b}{1 + b^2}
\]  
(19)

\[
\lim_{a \to 0} k_2 = \frac{-Db}{1 + b^2}
\]  
(20)

It is thus always possible to compute the terms \( k_1 \) and \( k_2 \) whatever the tether configuration. Then by injecting (15) into (7) we obtain the following relation:

\[
\begin{bmatrix}
\dot{w} \\
\dot{\mathbf{f}} \\
\dot{\mathbf{m}}
\end{bmatrix} = M \dot{s}
\]  
(21)

with

\[
M = \begin{bmatrix}
k_1 \cos \alpha & k_2 \cos \alpha & -D \sin \alpha \\
k_1 \sin \alpha & k_2 \sin \alpha & D \cos \alpha \\
n_1 & n_2 & 0
\end{bmatrix}
\]  
(22)

where \( n_1 = D^2 + t_2 k_1 \) and \( n_2 = D + t_2 k_2 \). The inverse of \( M \) can be analytically calculated and is given by:

\[
M^{-1} = \frac{1}{Dq} \begin{bmatrix}
-n_2 \cos \alpha & -n_2 \sin \alpha & k_2 \\
n_1 \cos \alpha & n_1 \sin \alpha & -k_1 \\
-q \sin \alpha & q \cos \alpha & 0
\end{bmatrix}
\]  
(23)

with \( q = Dk_2 - k_1 \).

From (21), we finally obtain the relation:

\[
\dot{s} = M^{-1} (\dot{w} \dot{\mathbf{f}} - \dot{w} \dot{\mathbf{m}}) = L \dot{v}
\]  
(24)

for ensuring an exponential decrease of the visual feature error \( \mathbf{e} = s - s^* \) toward zero \( \mathbf{e}^* \). Here \( s^* \) denotes the desired value of the visual features, \( \lambda (> 0) \) is the control gain, and \( L \) is the Moore-Penrose pseudoinverse of \( L \).

In case point \( p_f \) is static (which is the case considered for our real experiments), the controller reduces to:

\[
\dot{v} = -\lambda L^\dagger (s - s^*)
\]  
(25)

Note that apart the singular configurations exhibited in Section [II-D], \( M \) is always of full rank 3, which ensures that the system is globally asymptotically stable in case \( M \) is correctly evaluated in (25).

As can be seen from (22), matrix \( M \) depends on the visual features \( a, b, \alpha \) that are measured at each iteration of the control scheme, the tether length \( L \) that is constant and supposed to be known, and \( D \) that is varying. We thus need to estimate \( D \). There are two ways for that: the first would be to track the attachment points \( p_f \) and \( p_m \) and measure their 3D position. As already said, this would not be convenient because the camera would need to have both points in its field of view, which would reduce the range of possible applications. The second method relies on estimating \( D \) from (13). Since there is unfortunately no explicit form for the solution of this equation, we propose to numerically search for a zero of (13):

\[
D = \arg \min_{D \in \mathbb{R}} (f(D, a, b) - L)
\]  
(27)
by determining $D$ with a Newton method using the derivatives of the objective function \( f \). In practice, only a couple of iterations are needed to estimate the new value of $D$ at each iteration of the control loop by using its previous value as initial guess. We used $D = L/2$ for the very first image.

### D. Study of the singularities of $L_n$

In the following, we present a study on the possible singularities that the interaction matrix $L_n$ may encounter. The determinant of $M$ is given by:

$$\det M = D^2 q = D(2Dk - k_1)$$  \hspace{1cm} (28)

$M$ and thus $L_n$ are singular when $D$ is null, meaning that points $p_f$ and $p_m$ coincide or lay on the same vertical. This is logical since the angle $\alpha$ is no more defined in that degenerate case. Another singularity is reached for the condition $Dk_2 - k_1 = 0$. By using \(16\) and \(17\) this condition can be rewritten as:

$$D(\sqrt{1 + \tan^2 \alpha_f} + \sqrt{1 + \tan^2 \alpha_m}) = 2L$$  \hspace{1cm} (29)

with $\tan \alpha_f = t_2 = 2Da + b$ and $\tan \alpha_m = b$, where $\alpha_f$ and $\alpha_m$ are respectively the angles of the tangent of the parabola at point $p_m$ and $p_f$ (see Fig. 2).

![Fig. 2: Tangent of the parabola at points $p_m$ and $p_f$.](image)

Since $1 + \tan^2 \alpha = \frac{1}{\cos^2 \alpha}$, \(29\) is equivalent to

$$\frac{D}{\cos \alpha_f} + \frac{D}{\cos \alpha_m} = 2L$$  \hspace{1cm} (30)

Then, by combining \(30\) and \(13\), and using $\tan \alpha_f - \tan \alpha_m = 2Da$, we obtain:

$$\frac{\tan \alpha_f}{\cos \alpha_m} - \frac{\tan \alpha_m}{\cos \alpha_f} = \arcsinh \left( \frac{\tan \alpha_f}{\cos \alpha_m} - \frac{\tan \alpha_m}{\cos \alpha_f} \right)$$  \hspace{1cm} (31)

The singularity condition is given by the solution of \(31\), which exists in $\mathbb{R}$ if and only if

$$\frac{\tan \alpha_f}{\cos \alpha_m} = \frac{\tan \alpha_m}{\cos \alpha_f}$$  \hspace{1cm} (32)

Thus, the singularity occurs when $\alpha_m = \alpha_f$, meaning that the tether is taut. However, when the tether is taut, we directly obtain from \(19\) and \(20\) $q = Dk_2 - k_1 = D^2b/(1 + b^2)$. Apart from the previous exhibited configuration $D = 0$, this term vanishes only when $b = 0$, that is, when the tether is taut horizontally.

A similar analysis demonstrates two singular configurations only: when $p_f$ and $p_m$ coincide, and when the parabola degenerates into a vertical or horizontal straight line. The former configuration corresponds to a pure degenerate case that cannot occur in practice. The latter can be avoided by never specifying such a desired configuration.

### III. Features Extraction

In practice, the tether shape is estimated from RGB-D data. In particular, its RGB image together with the depth are used to fit a parabola into the observed point cloud of the tether. The image processing pipeline consists in first applying a classical hand-eye calibration technique \(\text{[18]}\). Using these 3D points $\mathbf{p}_1, \ldots, \mathbf{p}_N$, the parameters $\mathbf{n}$ and $\mathbf{d}$ of the plane equation $\mathbf{w}^T \mathbf{n} + \mathbf{d} = 0$ in $\mathcal{F}_w$ are estimated by using a robust least square method \(\text{[3]}\) for eliminating potential outliers due to depth measurement errors. Notice that we impose the $z$-component of the normal $\mathbf{w}_n$ to $\mathbf{w}_n z = 0$ during the estimation process since the plane is always vertical in $\mathcal{F}_w$ due to the gravity. The angle $\alpha$ is then directly given by:

$$\alpha = \arctan(-\mathbf{w}_n z/\mathbf{w}_n y)$$  \hspace{1cm} (33)

Afterwards, we use the cable plane equation expressed in the camera frame $\mathcal{F}_c$: $\mathbf{n}^T \mathbf{p} + c d = 0$ to reconstruct the 3D coordinates $\mathbf{p}_i$ of each point belonging to the middle line of the cable from its observed image coordinates $\mathbf{p}_{im} = (\tilde{x}_i, \tilde{y}_i, 1)$. Indeed, we have:

$$\mathbf{p}_i = (\tilde{x}_i z_i, \tilde{y}_i z_i, z_i)$$  \hspace{1cm} (34)

with

$$z_i = -\frac{c d}{\mathbf{n}^T \mathbf{p}_{im}}$$  \hspace{1cm} (35)

This process allows considering a new set of $N$ 3D points that are less tainted by the sensor depth measurement noise. Note that $\mathbf{n}^T \mathbf{p}_{im} = 0$ in \(35\) if and only if the cable plane is orthogonal to the image plane, which is a degenerate case we do not consider. Finally, the parabolic features $a$ and $b$ are estimated using a classical least squares method from this set of $N$ points expressed in $\mathcal{F}_c$. For doing that, the points are expressed in $\mathcal{F}_t$ using the transformation $\mathbf{H}_c = \mathbf{H}_w^{-1} \mathbf{H}_t$ where $\mathbf{H}_w$ is the inverse of the homogeneous transformation \(2\) that is computed using the estimated $\alpha$ and the 3D position of $p_m$ in $\mathcal{F}_w$ provided by the robot odometry. Furthermore, $a$ and $b$ are given by solving $a \mathbf{t} x_i^2 + b \mathbf{t} x_i = \mathbf{t} z_i, i = 1, \ldots, N$ whose solution is given by:

$$\begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} t_{x_1}^2 & t_{x_1} \\ \vdots & \vdots \\ t_{x_N}^2 & t_{x_N} \end{bmatrix}^{-1} \begin{bmatrix} t_{z_1} \\ \vdots \\ t_{z_N} \end{bmatrix}$$  \hspace{1cm} (36)
For using this model, we set arbitrary values for the Young’s modulus $E$, the tether cross-section $A$, and the tether mass per unit length $\rho$. These parameters correspond to the mechanical parameters of the cable that are required for the physics-based model [20]. From the known position of the two tether extremities, the corresponding external force $f$ with components $(f_x, 0, f_z)$ in $\mathcal{F}_t$ to be applied to the extremity point $p_m$ is first estimated (see Fig. 3). Then, the solution at static equilibrium of the forces applied to the tether, that is, the external force $f$ and the gravity $g$, allows determining the shape of the cable, from which a Point Cloud (PC) is generated. The coefficients $(a, b)$ of the parabola are then determined using the least squares method described in Section III and a next iteration of the control loop can be achieved. We use ViSP [12] for the implementation of the overall simulation.

The results of two shape servoing tasks are illustrated on Fig. 4. The first one is such that $s^* = [0, -0.7, 0]$, which means we want to reach a taut configuration, while the second one is such that $s^* = [3.6, -1, -30^\circ]$, which corresponds to a general configuration. In both cases, the initial configuration of the tether is set to $s_0 = [1.2, -1.4, 75^\circ]$. We can see the perfect exponential decrease of the error on Fig. 4a and 4b. The three translational velocities of $p_m$ depicted on Fig. 4e and 4f also show a nice behavior without any instabilities when the tether becomes taut. These simulation results demonstrate that our control solution based on an approximation of the tether shape with a parabola can accurately perform the task, whatever the desired configuration of the cable.

B. Experimental validation

The experimental setup is composed by an Omron© 6 DOF articulated robot Viper650 (see Fig. 5a). The left extremity of a 86 centimeters length cable is attached to the robot end-effector and the right one is fixed to a tripod. A remote Intel® D435 RGB-D with a resolution of 1280x720 pixels for both data streams is mounted on a second fixed tripod and observes the scene.

To validate our method two different tasks were tested: the first is to stretch the tether by setting $s^* = [0, -0.4, -30^\circ]$ and the second is to move it back to a slack configuration with $s^* = [1.5, -1.4, -15^\circ]$. The initial state is such that $s_0 = [1, -1.1, -17^\circ]$. The robot control sampling frequency is set to the camera frame rate (30 Hz) and the control gain is fixed to $\lambda = 0.5$. Typical RGB and depth images acquired by the camera are presented in Fig. 6. The temporal evolution of the features error together with the control velocity applied on point $p_m$ are shown on Fig. 6a (see also the accompanying video). One can see in Fig. 6a and 6b the exponential decoupled decrease of the features error to zero, which demonstrates the efficiency of the proposed approach. We can note on Fig. 6c and 6d that the noise on the estimated value of $\alpha$, which is due to the low accuracy of the depth measurements, induces some noise on the $v_x$.

Algorithm 1: Simulation of the proposed visual servoing

and $v_y$ components of the end-effector velocity, but without destabilizing the system. These results show that even if our approach is based on a coarse modelling of the tether cable by a parabolic curve, it can efficiently perform the shaping task thanks to the robustness of the shape servoing closed-loop control scheme.

V. CONCLUSION

In this paper, we addressed the automatic manipulation of a suspended tether cable. We proposed three visual features from a simple parabolic geometric model to control the translational velocities of its extremities. The analytical form of the related interaction matrix has been determined, allowing to demonstrate the absence of singularities apart when the tether is taut vertically or horizontally. Simulations together with real world tests have shown the efficiency of our method that does not require any knowledge of material mechanical properties. In comparison to model-free methods, the proposed approach has the advantage to provide a complete study of potential singular configurations and it gets rid of an online estimation of the shape Jacobian. Moreover it does not require any path planning for local minima avoidance and allows to bring the cable to taut configurations, which was not possible before.

In future work, we plan to extend this approach for controlling two quadrotors holding together a tether cable with the objective to grasp and manipulate objects for transport applications.

VI. ACKNOWLEDGEMENTS

The authors would like to thank Sébastien Briot who suggested to use the catenary model for simulations, as well as Isabelle Fantoni for useful discussions.
