Abstract—When graph database users explore unfamiliar graphs, potentially with heterogeneous structure, users may need to find how two or more groups of nodes are connected in a graph, even when users are not able to describe the connections. This is only partially supported by existing query languages, which allow searching for paths, but not for trees connecting three or more node groups.

In this work, we formally show how to integrate connecting tree patterns (CTPs, in short) with a graph query language such as GPML [1], SPARQL or Cypher, leading to Extended Queries (or EQs, in short). We then study a set of algorithms for evaluating CTPs: we generalize prior keyword search work to be complete, most importantly by (i) considering bidirectional edge traversal, (ii) allowing users to select any score function for ranking CTP results and (iii) returning all results. To cope with large search spaces, we propose efficient pruning techniques and formally establish a large set of cases where our best algorithm, MoLesP, is complete even with pruning. Our experiments validate the performance of our algorithms on many synthetic and real-world workloads.

Index Terms—Graph Queries, Graph Data Management, Keyword Search on Graphs

I. INTRODUCTION

Graph databases are increasingly adopted in many applications, e.g., social network analysis, scientific data exploration, the financial industry, etc. [2]. To query RDF graphs, the W3C’s standard SPARQL [3] query language is the best known. For property graphs (PG), the International Organization for Standardization (ISO) and International Electrotechnical Commission (IEC) are developing GQL, with the graph pattern matching sub-language (GPML) [1] at its core.

An interesting but challenging graph query language feature is reachability: a SPARQL 1.1 query can check, e.g., if there are some bank transfer paths, along which Mr. Shady eventually deposits funds into a given bank ABC. However, SPARQL 1.1 does not allow returning the matching paths to users. In contrast, a GPML query may also return the paths between two given sets of nodes. This is useful in investigative journalism applications [4], in the fight against money laundering, etc.

Unfortunately, none of these languages natively support finding trees, connecting three (or more) sets of nodes; this feature can be very useful. For instance, when investigating ill-acquired wealth, one may ask for “all connections between Mr. Shady, bank company ABC, and the tax office of country DEF”; an answer to this query is a tree, connecting three nodes corresponding to the person, bank, and tax office, respectively.

The above query has two parts: one structured, requiring that Mr. Shady be a person, ABC be the name of a bank and DEF that of a country, and an unstructured one, searching for connections between the nodes designated by the structured one. The unstructured part recalls keyword search in (relational, RDF or XML) databases: users specify m keywords, and request trees (or small graphs) connecting tuples (or nodes) from the database, such that a tuple attribute value (or node label) matches each keyword. Representative keyword search works include, e.g., [5]–[14]. Finding such trees is closely related to the Group Steiner Tree Problem (GSTP), which, given m node sets, asks for the top-score, e.g., fewest-edges, tree connecting one node from each set; the problem is NP-hard. To cope with the high complexity, existing keyword search algorithms: (i) consider a fixed score function and leverage its properties to limit the search, (ii) propose approximate solutions, within a known distance from the optimum, and/or (iii) implement heuristics with no guarantees, but which perform well in some cases.

Requirements From our collaborations with investigative journalists [4], [15], we identified some requirements. First, (R1) graph query languages should allow returning trees that connect m node sets, for some integer m ≥ 2; (R2) it must be possible to search for connecting trees orthogonally to (or, in conjunction with any) score function used to rank the trees. This is because different graphs and applications are best served by different scores, and when exploring a graph, journalists need to experiment with several before they find interesting patterns. In our example, if Mr. Shady is a citizen of DEF and ABC has offices there, the smallest solution connects them through the DEF country node; however, this is not interesting to journalists. Instead, a connection through three ABC accounts, sending money from DEF to Mr. Shady in country GHI, is likely much more interesting. An orthogonal requirement is (R3) to treat graphs as undirected when searching for trees. For instance, the graph may contain “Mr. Shady hasAccount acct1”, or, just as likely, “acct1 belongsTo Mr. Shady”. We should not miss a connecting tree because we “expected” an edge in a direction and it happens to be in the opposite direction. Further, (R4) all answers must be found for several reasons: (i) continuity with the semantics of graph query languages, that also return all results (unless users explicitly restrict them); (ii) to be able to score the

*Work done while at Ecole Polytechnique.
answers with the chosen function (recall R2). We call a tree search algorithm supporting (R2)-(R4) **complete**. For practical reasons, given the complexity, which is further exacerbated by (R3), we need to be able to limit the search by a time and/or space budget. Finally, (R5) our queries should be efficiently executed, even when graphs are highly heterogeneous, as in investigative journalism scenarios, where text, structured, and/or semistructured sources are integrated together.

**Contributions** To address the above requirements, we make the following contributions:

1. We formally integrate Connecting Tree Patterns (CTPs, in short) with conjunctive graph pattern queries, leading to **Extended Queries (EQs, in short)**. A CTP allows searching for trees that connect m groups of nodes, for m ≥ 2; they can be freely joined with graph patterns. This addresses requirements (R1), (R2), and also (R3), since our CTP semantics returns trees regardless of the edge directions (Sec. [II]).

2. For **complete CTP evaluation**, we study a set of baseline algorithms, and show that their performance suffers due to repeated (wasted) work and/or the need to minimize the trees they find; the GAM [15] algorithm is complete and more efficient, but it does not scale in all cases. We introduce a powerful **Edge Set Pruning (ESP) technique**, which significantly speeds up the execution, but can lead to incompleteness. We then bring two orthogonal modifications which, combined, lead to our MoLESP algorithm, for which we formally establish completeness for m ∈ {2, 3}, which are most frequent, as well as for a large class of results for arbitrarily large m. This addresses (R4) and contributes to (R5) (Sec. [IV]).

3. We experimentally show that: (i) baseline algorithms inspired from breadth-first search are unfeasible even for small graphs; (ii) MoLESP strongly outperforms the prior complete GAM algorithm [15]; (iii) integrating MoLESP with a simple conjunctive graph query engine allows to efficiently evaluate extended queries (Sec. [V]).

**II. EXTENDED QUERIES (EQS)**

We present connection search as a novel query primitive, and show how it integrates in GPML [1] graph querying.

**Definition II.1** (Graph). A graph is defined as a tuple G = (N, E, ρ, λ, π), where N consists of a finite set of node identifiers, E is a finite set of edge identifiers, ρ: E → (N × N) is a function mapping edges to ordered pairs of nodes, λ: (N ∪ E) → 2C is a function mapping nodes and edges to a set of labels, L and π: (N∪E) × P → Val is a partial function assigning values from Val to node and edge properties (P).

Fig. [I] introduces a sample graph, assigning an integer ID and label to each node and edge. We will refer to nodes as n1, n2, etc., e.g., n1 is the node whose ID is 1 and label is OrgB, and similarly to edges as e1, e2, etc.

**GPML graph querying** Let V be a set of variable names, and Ω = {=, <, ≤} be a set of comparison operators, used to express patterns over nodes or edges. At the core of GPML are path patterns (PPs, in short), such as the following:

\[
\text{MATCH } (v: \text{Alice WHERE } v.τ=\text{entrepreneur}) \rightarrow [c: \text{citizenOf}] \rightarrow (w \text{ WHERE } w.τ=\text{country})
\]

The above PP has two node patterns: (v: Alice WHERE v.τ=entrepreneur) and (w WHERE w.τ=country), specifying the conditions on, respectively, the start and the end points of the edge pattern [c: citizenOf] →. The source node pattern is satisfied by the node n3 in our example graph, while the target node pattern is satisfied by the nodes n4 and n10. The edge pattern is satisfied by the edges e5, e6, e12, e13, e14 and e20 as all of them have the label citizenOf. Together, the PP is satisfied by only the edge n3 e14 n8.

PPs may use path variables, which are bound to whole paths. For example, in the PP MATCH p = (x) −[y: founded]− (z) ←[(u: investsIn)]− (v), one of the bindings is as follows: p matches the path n4 e15 n7 e16 n6, x matches n4, y matches e10, z matches n7, u matches e9 and v matches n6.

GPML also supports regular path queries (RPs, in short). For example, MATCH p = (x) −[y: founded]−(z) matches all paths of 0 or more edges labeled founded. Infinitely many paths (even cyclic ones) may match an RP. To ensure finite results, GPML provides restrictors, namely: TRAIL (no repeated edges), ACYCLIC (no repeated nodes) and SIMPLE (no repeated nodes except that it could be a loop). If no restrictor is used, GPML mandates limiting RP results through a selector, e.g., ANY k for at most k results. A **GPML graph pattern** (GP, in short) is a set of several PPs such that each PP shares a variable with at least one other PP.

GPML generalizes both RDF query languages such as SPARQL 1.1 and property graph query languages such as Cypher; significantly, GPML allows binding variables to paths and thus returning them. However, it does not allow searching for arbitrary connections between more than two variables.

**Extending GPML:** Connecting Tree Patterns To extend GPML’s expressive power, we introduce:

**Definition II.2** (CT Pattern). A connecting tree pattern (CTP, in short) is a tuple of m+1 distinct variables of the form: (v1, v2, …, vm, vm+1). Intuitively, CTPs extend the path patterns by enabling connectivity search between more than 2 nodes, as follows. When replacing each vi, 1 ≤ i ≤ m with a graph node, vm+1 is bound to a subtree of G, having these nodes as leaves (we formalize this below). To visually
distinguish the last variable in a CTP, we always underline it.

For example, consider the CTP \( (x, y, z, w) \); on replacing \( x \) with \( n_3, y \) with \( n_9 \) and \( z \) with \( n_{12} \), one subtree bound to \( w \) is the tree \( t_\alpha \) consisting of the edges \( n_3 \xrightarrow{\epsilon_{12}} n_{11} \xrightarrow{\epsilon_{10}} n_9, n_{11} \xrightarrow{\epsilon_{18}} n_{12} \). Tree \( t_\alpha \) is one connection between the three nodes, via \( n_{11} \).

We extend GPML to allow CTPs alongside GPs:

**Definition II.3** (Extended query). An extended query \( Q \) is a set of \( k \) GPs, \( k \geq 0 \), and \( l \) CTPs, \( l \geq 0 \), such that \( k + l > 0 \), the variables in the GPs are pairwise disjoint, and each underlined (last) variable from a CTP appears exactly once in \( Q \).

Below, we simply use “query” to designate an extended one.

A sample query \( Q_1 \), of three GPs and one CTP, is:

\[
\begin{align*}
\text{MATCH} & \quad (x \text{ WHERE } x.\tau = \text{entrepreneur} \rightarrow \{a: \text{citizenOf}\rightarrow \{b: \text{USA}\},
\text{y WHERE } y.\tau = \text{entrepreneur} \rightarrow \{c: \text{citizenOf}\rightarrow \{d: \text{France}\},
\text{z WHERE } z.\tau = \text{politician} \rightarrow \{e: \text{citizenOf}\rightarrow \{f: \text{France}\},
(x, y, z, w)\}
\end{align*}
\]

asks: “What are the connections \( w \) between some American entrepreneur \( x \), some French entrepreneur \( y \), and some French politician \( z \)?” We denote the CTP of this query by \( g^1 \).

**Definition II.4** (Set-based CTP result). Let \( g = \{v_1, \ldots, v_m, v_{m+1}\} \) be a CTP pattern and \( S_1, \ldots, S_m \) be sets of \( G \) nodes, called seed sets. The result of \( g \) based on \( S_1, \ldots, S_m \), denoted \( g(S_1, \ldots, S_m) \), is the set of all \( (s_1, \ldots, s_m, t) \) tuples such that \( s_i \in S_1, \ldots, s_m \in S_m \) and \( t \) is a minimal subtree (thus, acyclic) of \( G \) containing the nodes \( s_1, \ldots, s_m \). By minimal, we mean that (i) removing any edge from \( t \) disconnects it and/or removes some \( s_i \) from \( t \), and (ii) \( t \) contains only one node from each \( S_i \).

Minimality condition (ii) follows from application requirements, e.g., a minimal connection between a person and a company should not include other companies. If connections between more people and companies are sought, they can be obtained by joining more CTPs and/or GPs.

In Fig. 1, let \( S_1 = \{n_2, n_4\} \) (US entrepreneurs), \( S_2 = \{n_3, n_6\} \) (French entrepreneurs), and \( S_3 = \{n_9, n_{12}\} \) (French politicians). Then, \( g^1(S_1, S_2, S_3) \) includes \( \{n_4, n_6, n_{12}, t_\beta\} \) where the tree \( t_\beta \) consists of the edges \( n_4 \xrightarrow{\epsilon_{10}} n_7 \xrightarrow{\epsilon_{19}} n_6, n_7 \xrightarrow{\epsilon_{10}} n_{12} \), also denoted by \( \{e_{10}, e_{19}, \epsilon_{19}\} \) for brevity. Another result of this CTP is \( (n_2, n_3, n_9, t_\gamma) \), with \( t_\gamma = \{e_1, e_2, e_{17}, e_{10}\} \). This result only exists because Def. II.4 allows trees to span over \( G \) edges regardless of the edge direction. Had it required directed trees, \( t_\gamma \) would not qualify, since none of its nodes can reach the others through undirected paths.

The above definition allows arbitrary seed sets, in particular, an \( S_i \) can be \( N \), the set of all graph nodes (Sec. IV-E2). We adjust Def. II.4 to allow a connecting tree to have any number of nodes from those seed sets equal to \( N \) (otherwise, only 1-node trees would appear in results).

The semantics of a PP \[\] is a table, associating to each variable \( v \) a graph node, edge, or path, which, together, satisfy the PP. The semantics of a GP is the natural join of its PP results, e.g., the variables in the GPs of \( Q_1 \) are bound to:

**EQ semantics** is defined by joining the GP semantics with the CTP set-based semantics, leading to a direct evaluation strategy as follows. Assume that evaluating all the GPs in the EQ, and joining their results, leads to a table of bindings as above, where each node variable \( v_i \) is successively bound to a set of nodes; call that set \( S_i \). This provides seed sets for each of the CTPs in the EQ, whose set-based results can thus be computed (Def. II.4). The EQ result is obtained as the natural join of all the GP and CTP results, on their shared variables. In our example, GP semantics provide \( S_1 = \{n_4\}, S_2 = \{n_6\} \) and \( S_3 = \{n_{12}\} \) to the CTP; CTP evaluation binds \( w \) to the tree having the edges \( n_4 \xrightarrow{\epsilon_{10}} n_7 \xrightarrow{\epsilon_{19}} n_6, n_7 \xrightarrow{\epsilon_{10}} n_{12} \); the EQ semantics extends the above table with the binding of \( w \). This evaluation strategy pushes (applies) all possible GP conditions on the CTP node variables prior to CTP evaluation.

**Restricting CTP results** A CTP can have a very large number of results, as illustrated by the graph in Fig. 2. For example, consider the node labelled “1” and \( v_2 \) to the node labelled “N+1”, the CTP \( (v_1, v_2, v_3) \) has \( 2^N \) solutions, or \( 2^{|E|/2} \), which grows exponentially in \( |E| \), the number of graph edges. Observe that if we allowed only unidirectional paths, there would be only \( N + 1 \) results, rooted at each node. This shows that matching CTPs regardless of the edge direction may drastically increase the number of CTP results, and also the number of partial trees to explore before finding the results. In such cases, complete CTP result computation may be unfeasible. To control the amount of effort spent evaluating CTPs, similarly to GPML’s restrictors, one may specify: that all paths must go from a CTP result root to its leaves (unidirectional paths, through the keyword UNI); that only a fixed set of labels (LABEL \( a_1, a_2, \ldots \)) are allowed on the edges in a CTP result. We also extend the
(non-deterministic) GPML selector ANY $k$ to a CTP, specifying that any $k$ results can be returned; finally, TIMEOUT $T$ stops execution and returns the results found after $T$ milliseconds.

A CTP may be associated a score function $\sigma$, assigning to each result tree $t$ a real number $\sigma(t)$ (the higher, the better). Specifying (for a given CTP or for the whole query) SCORE $\sigma$ [TOP $k$] means that the results of each CTP must be scored using $\sigma$, and the scores included in the query result. If TOP $k$ is used, only the $k$ highest-score trees are returned.

Since the GPs can be evaluated by any conjunctive graph query evaluation engine, in the remainder of the paper, we focus on efficient evaluation of set-based CTP results (Def. III.4). Table I recaps all the notations used in the paper.

### III. CTPs COMPARED TO EXISTING LANGUAGES

We now discuss how close existing graph query languages come to allowing their users to ask for connection between several seed sets, in the spirit of CTPs. First, observe that languages such as SPARQL or CRPOQs [10], [17], that do not allow returning a path of unspecified length, cannot be used.

Other languages, e.g., the JEDI extension of SPARQL [18], G-CORE [19], or GPML [1], allow returning such paths. To see how close this comes to CTPs, assume a GQL query identifies two seed sets $S_1$, $S_2$, and asks for all acyclic paths between a node from $S_1$ and one from $S_2$. Some such paths may not be results of a CTP with the seed sets $S_1$ and $S_2$: a path going from $s_1 \in S_1$ through $s'_1 \in S_1$ to $s_2 \in S_2$ violates minimality condition (ii) from Def. III.4. To ensure this minimality, we should check that each path has exactly one node from $S_1$ (at one end), but not more, and similarly for $S_2$. Depending on the language syntax, this may be more or less easy to express.

Next, consider a CTP $g = (v_1, v_2, v_3, v_4)$ and three seed sets $S_1, S_2, S_3$ (the discussion is similar for more seed sets). In GPML, we can use three path patterns going from a common variable $r$, to a node from $S_1$, one from $S_2$ and one from $S_3$, respectively, to obtain triplets of paths joined on a common node matching $r$. We call this approach for finding connections among the seed sets, path stitching. Clearly, each of its results needs to be filtered for minimality, as explained above. However, path stitching results for three or more seed sets differ even more from $g''((S_1, S_2, S_3))$ [20], [21]: (i) for each $n$-nodes tree in $g''((S_1, S_2, S_3))$, path stitching produces $n$ trees (with the same edges, but different roots); deduplication based on the set of edges is then needed; (ii) if a path from $r$ to $s_1$ shares nodes or even edges with a path from $r$ to $s_2$ and/or the one from $r$ to $s_3$, the join of these paths is not a tree, but a graph, from which one or several CTP results may be extracted. This is a second, independent reason why trees obtained through path stitching must be globally deduplicated.

As our experiments show (Sec. V-E), even ignoring deduplication and minimization, path stitching is outperformed by our algorithms, where result tree minimality is built-in.

Finally, note that while our CTPs have the core restrictions useful in our application scenarios, languages such as Cypher [22], G-CORE [19], GPML [1] provide more controls over: edge direction, presence of cycles, allowed edge labels, path length etc. One could adapt them to CTPs, with the semantics that they should apply on each path in a CTP result.

### IV. COMPUTING SET-BASED CTP RESULTS

We aim to find all the minimal subtrees with exactly one node (or seed) from each $S_i$, limited only by the time and memory allowed to the search. As we detail in Sec. VII, most current algorithms require a regular graph structure, and/or find only one, or few subtrees, those minimizing (or $k$-optimal w.r.t.) a fixed score function. Below, Sec. IV-A to IV-C recall existing algorithms which find all results. In Sec. IV-D to IV-G, we propose novel algorithms, much more efficient, but which may, in worst-case scenarios, lead to missing certain results. Sec. IV-H shows how restrictors, selectors and score functions can be injected in our algorithms. We briefly discuss how to handle the special case of very large seed sets, in Sec. IV-I.

**Observation 1.** Let us call leaf any node in a tree that is adjacent to exactly one edge. It is easy to see that in each CTP result, every leaf node is a seed. Clearly, the converse does not hold: in a result, some seeds may be internal nodes. We denote by $\text{sat}(t)$ the node sets from which $t$ has a seed.

**Observation 2.** When users limit the search time and/or number of desired results, it is reasonable to return at least the smallest-size ones, given that smaller trees are favored by many score functions (see Sec. VII). However, we do not assume “smaller is always better”: that is for the score function $\sigma$ to decide. Nor do we require users to specify a maximum result size, which may be hard for them to guess. Rather, we investigate algorithms that find as many results as possible, as fast as possible, while also leveraging restrictors and selectors (when specified) to reduce the evaluation effort.

**A. Simple Breadth-First algorithm (BFT)**

A natural approach to find trees connecting seed sets is to explore the graph in breadth-first (BF) mode starting from each seed; when search paths starting from one seed of each set meet, a result is found. This approach has been taken by many non-complete algorithms, e.g., [7] [9] [23] and others, which also use score-based heuristics to limit the search. Independent of a score and aiming for completeness, we devise the following simple algorithm, which we call BFT. Start by creating a generation of trees $T_0$, containing a one-node tree, denoted INIT $(n)$, for each seed node $n \in S_1 \cup \ldots \cup S_m$. Then, from each generation $T_i$, build the trees $T_{i+1}$, by “growing” each tree $t$ in $T_i$, successively, with every edge $(n, n')$ adjacent to one of its nodes $n \in t$, such that:

- (GROW1): $n'$ is not already in $t$, and
- (GROW2): $n'$ is not a seed from a set $S_j \in \text{sat}(t)$.

Condition (GROW1) ensures we only build trees. (GROW2) enforces the CTP result minimality condition (ii) (Def. III.4). As trees grow from their original seed, they can include more seeds. When a tree has a seed from each set, it must be minimized, by removing all edges that do not lead to a seed, before reporting it in the result. For instance, with the seed sets $\{n_2\}$ and $\{n_4\}$ on the graph in Fig. 1 starting from $n_2$, BFT
may build \( \{ e_5, e_4 \} \), then \( \{ e_5, e_4, e_6 \} \) before realizing that \( e_4 \) is useless, and removing it through minimization. Minimization slows BFT down, as we experimentally show in Sec. V-D.

BFT can build a tree in multiple ways; to avoid duplicate work, any tree built during the search must be stored, and each new tree is checked against this memory of the search.

It is easy to see that BFT is complete, i.e., given enough time and memory, it finds all CTP results.

### B. GAM algorithm

The GAM (Grow and Aggressive Merge) algorithm has been introduced recently [15], reusing some ideas from [9]. Unlike BFT that views a tree as a set of edges, GAM distinguishes one root node in each tree it builds. GAM inserts in a priority queue \( \text{GROW} \) opportunities, as (tree, edge) pairs such that the tree could grow from its root with that edge. Any priority can be used in the queue to choose a desired exploration order without affecting the results.

GAM also starts from the set of \text{INIT} trees built from the seed sets. Next, it inserts in the priority queue all \((t, e)\) pairs for some \text{INIT} tree \( t \) and edge \( e \) adjacent to the root (only node) of \( t \), satisfying the conditions \((\text{GROW}1)\) and \((\text{GROW}2)\) introduced in Sec. IV-A. GAM then repeats the following, until no new trees can be built, or a time-out is reached:

1. \((\text{GROW})\): Pop a highest-priority \((t, e)\) pair from the queue, where \( e \) connects \( t.\text{root} \) to \( n' \), and build the tree \( t' \) having the edges of \( t \) as well as \( e \), and rooted in \( n' \).
2. \((\text{MERGE})\): For any tree \( t^{ii} \) already built, such that:
   a. \((\text{MERGE}1)\): \( t^{ii} \) has the same root as \( t^{i} \), and no other node in common with \( t^{i} \); and
   b. \((\text{MERGE}2)\): \( sat(t') \cap sat(t^{ii}) = \emptyset \),

   take the following steps:
   a. Build \( t^{iii} \), a tree having the edges of \( t^{i} \) and those of \( t^{ii} \), and the same root as \( t^{i} \) and \( t^{ii} \);
   b. Immediately \( \text{MERGE} t^{iii} \) with all qualifying trees (see conditions \((\text{MERGE}1)\) and \((\text{MERGE}2)\)), and again merge the resulting trees etc., until no more \( \text{MERGE} \) are possible;
3. For each tree \( t^{iv} \) built via \text{GROW} or \text{MERGE} as above:
   a. if \( t^{iv} \) has a seed from each set, report it as a result;
   b. otherwise, push in the priority queue all \((t^{iv}, e^{iv})\) pairs such that \( e^{iv} \) is adjacent to the (only) root node of \( t^{iv} \), satisfying the conditions \((\text{GROW}1)\) and \((\text{GROW}2)\).

Property 1 (GAM completeness). The GAM algorithm is complete.

Property 2 (GAM result minimality). By construction, each result tree built by GAM is minimal (in the sense of Def. IV.4).

Thus, GAM does not need to minimize the results it finds.

### Search space exploration order

Unlike BFT, GAM does not build trees in the strictly increasing order of their size; MERGE may build large trees before other, smaller trees. The order in which GAM enumerates trees is determined, first, by the priority of the queue with \((t, e)\) entries, and second, by the available \( \text{MERGE} \) opportunities. In this work, to remain compatible with any score function, we study search algorithms regardless of (orthogonally to) the search order.

GAM may also build a tree in multiple ways. Formally:

**Definition IV.1** (Tree with provenance). A tree with provenance (or provenance, in short) is a formula of one of the forms below, together with a node called the provenance root:

1. \text{INIT} \((n_1)\) where \( n \) is a seed; the root of such a provenance is \( n \) itself;
2. \text{GROW} \((t, e)\) where \( t \) is a provenance, its root is \( n_0 \), \( e \) is an edge going from \( n_0 \) to \( n_1 \) and \( n_1 \) does not appear in \( t \); in this case, \( n_1 \) is the root of the \( \text{GROW} \) provenance;
3. \text{MERGE} \((t_1, t_2)\), where \( t_1 \) and \( t_2 \) are provenances, rooted in \( n_1 = n_2 \); in this case, \( n_1 \) is the root of the \( \text{MERGE} \) provenance.

We call rooted tree a set of edges that, together, form a tree, together with one distinguished root node. GAM may build several provenances for the same rooted tree, e.g., \text{MERGE} \((t_1, t_2, t_3)\) and \text{MERGE} \((t_2, \text{MERGE} (t_1, t_3))\), for some trees \( t_1, t_2, t_3 \). The interest of a tree as part of a possible result does not depend on its provenance. Therefore, GAM discards all but the first provenance built for a given rooted tree.

### C. BFT variants with MERGE

The \text{MERGE} operation can also be injected in the BFT algorithm to allow it to build some larger trees before all the smaller trees have been enumerated. We study two variants: BFT-M merges each new tree resulting from \text{GROW} with all partners having only one common node and no common edges (Step 2a) in Sec. IV-B, but does not apply \text{MERGE} on top of these provenances; in contrast, BFT-AM applies both Step 2a and Step 2b to aggressively merge. BFT-M and BFT-AM are obviously complete. Like BFT, they still need to minimize a potential result before reporting it. This is because BFT algorithms grow trees from any of their nodes, thus may add edges on one side of one seed node, which later turn to be useless. GAM avoids this by growing only from the root.

**D. Edge set pruning and ESP algorithm**

GAM may build several rooted trees for the same set of edges. For example, on the graph in Fig. 3 with the seeds \{B\}, \{C\}, denoting a rooted tree by its edges and underlining the root, successive \text{GROW} from B lead to B-3-C, \text{GROW}'s from C lead to B-3-C, and \text{MERGE} of two \text{GROW} provenances, B-3 and 3-C yields B-3-C. However, the root is meaningless in a CTP result, which is simply a set of edges. We introduce:

**Definition IV.2** (Edge set). An edge set is a set of edges that, together, form a tree such that at most 1 leaf is not a seed.

A result is a particular case of edge set, where all leaves are seeds (recall Observation 1).

As GAM builds several rooted trees for an edge set, it repeats some effort: we only need to find each result once. This leads to the following pruning idea:

**Definition IV.3** (Edge-set pruning (ESP)). The ESP pruning technique during GAM consists of discarding any provenance
$t_1$ whose edge set is non-empty, such that another provenance $t_0$, for the same edge set, had been created previously.

We will call ESP, in short, the GAM algorithm (Sec. IV-B) enhanced with ESP. As we will show, **ESP significantly speeds up GAM execution**. However, ESP compromises **completeness** for some graphs, seed sets, and execution orders. That is: depending on the order in which trees are built, the first (and only, due to ESP) provenance for a given edge set may prevent the algorithm from finding some results.

For instance, on the graph in Fig. 3 with the seed sets $S_1=\{A\}$, $S_2=\{B\}$, $S_3=\{C\}$, a possible GAM execution is:

1) Initial trees: $A$, $B$, $C$.
2) A set of GROW lead to these trees: $A-1$, $B-2$, $B-3$, $C-3$.
3) $B-3$ and $C-3$ merge into $B-3-C$.
4) GROW on $A-1$ leads to $A-1-2$, which immediately merges with $B-2$, forming $A-1-2-B$.
5) After this point:
   - If the tree $A-1-2-B$ is built, for instance by GROW on $A-1-2$, ESP discards it since $A-1-2-B$ was found in step (4). Lacking $A-1-2-B$, we cannot GROW over it to build the result provenance $A-1-2-B-3-C$. Nor can we build the result provenance MERGE ($A-1-2-B$, $B-3-C$).
   - By a similar reasoning, when $B-3-C$ is built, it is discarded by ESP, preventing the construction of $A-1-2-B-3-C$.

Thus, no result is found.

Note that with a favorable execution order, the CTP result would be found. For instance, from $\{A$, $B$, $C\}$, ESP could build:

2) MERGE ($A-1-2-B$, $C-3-B$) is a provenance for the result.

This raises the question: can we pick a GAM execution order that would ensure completeness, even when using ESP? Intuitively, the order should ensure that for each result $r$, a provenance $p_r$ is certainly built, which requires that at every sub-expression $e$ of $p_r$, over an edge set $es$, the first provenance $p_{es}$ for $es$ is rooted in a node that allows to build on $e$ until $p_r$.

Thus, the decisions made up to building $p_{es}$ would need to have a “look-ahead” knowledge of the future of the search, which is clearly not possible. In the above example, the “bad” order builds $A-1-2-B$ first, instead of the favorable $A-1-2-B$. However, when exploring these three edges, we cannot “pre-determine” the best provenance for $es$. Recall also from Sec. IV-B that different orders may be suited for partial exploration with different score functions. In a conservative way, we consider an algorithm incomplete when for some “bad” execution order it may miss results.

ESP finds some answers for any execution order:

**Property 3 (2-seed sets ESP completeness).** Let $t$ be a result of a CTP with 2 seed sets. Then, $t$ is guaranteed by ESP.

Here and throughout this paper, **guaranteed**, for a rooted tree or an edge set, means that at least one provenance for it is built; the first is not pruned by ESP. This and other proofs of our claims can be found in our technical report [24].

CTP with two seed sets (path queries) are frequent in practice; on these, GAM [15] and ESP are comparable, and we experimentally show the latter is much more efficient. Next, we refine our algorithms to extend our completeness guarantees.

### E. MoESP Algorithm

We now introduce an algorithmic variant called **Merge-oriented ESP**, or MoESP, which finds many (but not all) CTP results for arbitrary numbers of seed sets.

MoESP works like ESP, but it creates more trees. Whenever GROW or MERGE produces a provenance $t$ having strictly more seeds than any of its (one or two) children, the algorithm builds from $t$ all the so-called **MoESP trees** $t'$ such that:

- $t'$ has the same edges (and nodes) as $t$, but
- $t'$ is rooted in a seed node, distinct from the root of $t$.

The provenance of any such $t'$ is denoted $MO(t, r)$ where $Mo$ is new symbol and $r$ is the root of $t'$. Within MoESP, **MERGE is allowed on MoESP trees, but not GROW**. More generally, GROW is disabled on any tree whose provenance includes $Mo$ as our MoESP completeness guarantees (Prop. 5) do not rely on GROW over such trees.

Clearly, MoESP builds a strict superset of the rooted trees created by ESP (thus, it finds all results of ESP). It also finds the result in Fig. 3. Namely, after creating $A$, $B$, $C$:

1) GROW leads to the trees: $A-1$, $B-2$, $B-3$, $C-3$.
2) $B-3$ and $C-3$ merge into $B-3-C$. MoESP trees are added at this point: $B-3-C$ and $B-3-C$.
3) GROW on $A-1$ leads to $A-1-2$, which merges with $B-2$, into $A-1-2-B$. We similarly get $A-1-2-B$ and $A-1-2-B$.
4) $A-1-2-B$ merges with $B-3-C$, leading to the result.

We now generalize the example by establishing completeness guarantees for MoESP.

**Definition IV.4** (Simple and $p$-simple edge set). A simple edge set is an edge set (Def. IV.2) where each leaf is a seed and no internal (non-leaf) node is a seed. A simple edge set is $p$-simple, for some integer $p$, if it has at most $p$ leaves.

For instance, on the sample graph in Fig. 4 and the 6 seed sets $\{A\}$, $\{B\}$, $\{C\}$, $\{D\}$, $\{E\}$, $\{F\}$, 2-simple edge sets are: A-4-D, shown in red; A-1-2-B, shown in blue; B-8-F, etc.

**Definition IV.5** (Simple tree decomposition of a solution). Let $t$ be a CTP result. A simple tree decomposition of $t$, denoted $\theta(t)$, is a set of simple edge sets which (i) are a partition of the edges of $t$ and (ii) may share (leaf) nodes with each other.

For instance, in Fig. 4 the red, blue, and violet edges, together, form a result for the 6-seed sets CTP. A simple tree...
Fig. 5: MoESP(left) and LESP(right) incompleteness example. The sample result above in Fig. 4 is 2ps, since its simple tree decomposition only contains 2-simple edge sets. The following important MoESP property guarantees it is found:

Property 4 (MoESP finds 2-piecewise simple solutions). For any number of seed sets $m$, MoESP is guaranteed to find any 2-piecewise simple result.

For a CTP with any number of $m$ seed sets, a path result is a simple tree (provenance $t$) in which no node has more than two adjacent edges. In a path result, the two ends of the paths are seeds, while internal nodes may be seeds, or not. Thus, any path result is 2ps. It follows then, as a direct consequence of Prop. 4:

Property 5 (MoESP finds all path results). For any CTP, MoESP finds all the path results.

However, outside 2ps results, MoESP may still fail. For instance, consider the graph in Fig. 3 and the seed sets $\{A\}, \{B\}, \{C\}$. The only result here is 3-simple. A possible MoESP execution order is:

1. Starting from $A, B, C$, GROW produces $A-1, B-2, C-3$;
2. $B-2-x$, followed by $B-2-x-3$, which merges with $C-3$ into $B-2-x-3-C$, leading also to $B-2-x-3-C$ and $B-2-x-3-C$;
3. $B-2-x-1$ which merges with $A-1, B-2-x-1-A$ and similar trees rooted in $B$ and $A$;
4. GROW produces $A-1-x$, ESP discards the MERGE of $A-1-x$ with $B-2-x$, due to the rooted tree built at step (3), over the same set of edges;
5. $A-1-x-3$ is built, then MERGE with $C-3$ creates $A-1-x-3-C$, and similar trees rooted in $A$ and $C$;
6. GROW produces $C-3-x$, ESP discards the merges of $C-3-x$ with $A-1-x$ due to the 3-rooted tree built at step (5) and with $B-2-x$ due to the 3-rooted tree built at step (2);
7. At this point, we have trees with two seeds, rooted in $A, B, C$. GROW on any of them is impossible, because they already contain all the edges adjacent to their roots. There are no MERGE possibilities on their roots, either. Thus, the search fails to find a result.

At steps (4) and (6), ESP is “short-sighted”: it prevents the construction of trees necessary for finding the result. Next, we present another optimization which prevents such errors.

F. LESP algorithm

The Limited Edge-Set Pruning (LESP, in short) works like ESP (Sec. IV-D), but it limits edge-set pruning, as follows.

- We assign to each node $n$, and maintain during LESP execution, a seed signature $ss_n$, indicating the seed sets $S_i, 1 \leq i \leq m$, such that a rooted path has been built from a seed $s_i \in S_i$, to $n$, since execution started. For any seed $s \in S_i$, the signature $ss_s$ is initialized with a 1 at each $i$ such that $s \in S_j$ ($m$ may belong to several seed sets), and 0 in the remaining positions. For a non-seed $n$, initially $ss_n = 0$; the $i$-th bit is set to 1 when node $n$ is reached by the first rooted path from a seed in $S_i$.

- Prevent ESP from discarding a MERGE tree rooted in $n$ such that: (i) there are at least 3 bits set to 1 in $ss_n$; and (ii) $n$ has at least 3 adjacent edges in $G$.

Intuitively, the condition on $ss_n$ encourages merging on nodes already well-connected to seeds. We denote by $d_n$ the number of $G$ edges adjacent to $n$; it can be computed and stored before evaluating any query. The condition on $d_n$ focuses the “protection against ESP” to MERGE trees rooted in nodes where such protection is likely to be most useful: specifically, those where 3 or more rooted paths can meet (see Lemma IV.1 below). GROW and MERGE apply on trees “spared” in this way with no restriction.

Clearly, LESP creates all the trees built by ESP, and may create more. In particular, reconsider the graph in Fig. 3, the associated seed sets, and the execution steps we traced in Sec. IV-E. At step (2), $ss_x$ is initialized with 010 (there is a path from $B$ to $x$). At step (4), when $A-1-x$ is built, $ss_x$ becomes 110; since $\sum ss_x = 2$, the tree $A-1-x-2-B$ is pruned. However, at step (6), when $C-3-x$ is built, $ss_x$ becomes 111, which, together with $d_x = 3$, spares its MERGE result $A-1-x-3-C$ (despite the presence of several trees with the same edges). In turn, this merges immediately with $B-2-x$ into a result.

We formalize the guarantees of LESP as follows.

Definition IV.7 ((u, v) rooted merge). For an integer $u \geq 3$ and non-seed node $n$, the $(u, v)$ rooted merge is the rooted
tree resulting from merging a set of \((u, s_i)\) rooted paths, for some seeds \(s_1, \ldots, s_u\).

It follows from the \((\text{MERGE}2)\) pre-condition (Sec. [IV-B]) that in an \((u, n)\) rooted merge, each \(s_i\) is from a different seed set. Further, it follows from the definition of an \((n, s_i)\)-rooted path, that in a \((u, n)\) rooted merge, all seeds are leaves. In other words, a \((u, n)\) rooted merge is a \(u\)-simple edge set.

Lemma IV.1. Any \((3, n)\) rooted merge is guaranteed to be found by LESP.

Property 6. For any integer \(u \geq 3\) and non-seed node \(n\), any \((u, n)\) rooted merge is guaranteed to be found by LESP.

For \(\geq 4\) seed sets, LESP may miss results that are not \((u, n)\) rooted merges. For instance, consider the following execution order for \(S=(\{A\}, \{B\}, \{C\}, \{D\})\) on the graph in Fig. 5:

2. GROW builds B–2–1–merging with A–1 into A–1–2–B.
4. GROW builds: A–1–2–B–2–x which cannot merge with B–2 due to A–1–2–B, and \(\sum(s_{2j})=2\); D–4–3 which cannot merge with C–3 as C–3–4–D exists, and \(\sum(s_{2j})=2\).
6. C–3–x–2 merges with A–1–2, leading to C–3–x–2–1–A; and B–2, leading to C–3–x–2–B.
7. Similarly, B–2–x–3, aggressively merges with C–3, leading to B–2–x–3–C, and D–4–3, leading to B–2–x–3–D.
8. Progressing similarly, we can only merge at most 3 rooted paths, in nodes 2, x or 3. We cannot merge with a path leading to the 4th seed, because the trees with the edge sets A–1–2–B and C–3–4–D, built at 2, 3 above, are not rooted in 2 nor 3, respectively, and these are the only nodes satisfying the LESP condition that “spares” some MERGE trees.

G. MoLESP algorithm

Our last algorithm, called MoLESP, is a GAM variant with ESP and both the modifications of MoESP (which injects more trees) and LESP (which avoids ESP pruning for some MERGE trees). Clearly, MoLESP finds all the trees found by MoESP and LESP.

Further:

Property 7 (MoLESP finds all 3ps results). MoLESP is guaranteed to find all the 3-piecewise simple results.

As an important consequence:

Property 8. MoLESP is complete for \(m \leq 3\) seed sets.

Our strongest completeness result is:

Property 9 (Restricted MoLESP completeness). For any CTP of \(m \geq 1\) seeds, MoLESP finds any result \(t\), such that: each edge set \(es \in \theta(t)\) is a \((u, n)\)-rooted merge (Def. [IV.7]), for some integer \(1 \leq u \leq m\) and non-seed node \(n\) in \(es\).

For example, in Fig. 6 with the six seeds \(A\) to \(F\), the result is guaranteed by MoLESP. Depending on the exploration order, MoESP and LESP may not find it.

Algorithm 3: Procedure \textsc{recordForMerge}(tree \(t\))

1. Add \(t\) to \textsc{TreesRootedIn}[t.root];
2. for \(n \in \{\text{nodes}(t) \cap \cup_i(S_i)\}\)
6. \textbf{if} \(\not\exists t \in \textsc{TreesRootedIn}[n]\) \textbf{then}
7. \textbf{return} false;
8. \textbf{end}
9. return true;
10. \textbf{end}

Algorithm 4: Procedure \textsc{isNew}(tree \(t\))

1. if \(t \not\in \textsc{Hist}\) \textbf{then}
2. \textbf{return} true;
3. \textbf{end}
4. if \(\not\exists t \in \textsc{TreesRootedIn}[\text{t.root}]\) \textbf{then}
5. \textbf{return} true;
6. \textbf{end}
7. \textbf{return} false;

MoLESP algorithm Algorithms [1] to [5] together, implement MoLESP. They share global variables whose names start with an uppercase: Res, PrioQ, Hist (the search history), and \textsc{TreesRootedIn} (to store the trees by their roots); the latter is used to find \textsc{merge} candidates fast. Variables with lowercase names are local to each algorithm. \textsc{ProcessTree} feeds the priority queue with (tree, edge) pairs at line [11] \textsc{recordForMerge} injects the extra MoESP trees (Sec. [IV-E] at lines [2] to [4]). \textsc{isNew} implements limited edge-set pruning based on the history, and the two conditions that can “spare” a tree from pruning (Sec. [IV-F]). \textsc{mergeAll} implements aggressive merging; by calling \textsc{ProcessTree} on each new \textsc{merge} result, through \textsc{recordForMerge}, the result is available in the future iterations of \textsc{mergeAll}.

H. CTP evaluation with restrictors and score function

We now briefly explain how various restrictors (Sec. [II]) can be inserted in the above algorithms. UNI-directional search is enforced by adding pre-conditions to \textsc{grow} and \textsc{merge}, to ensure we only create the desired provenances. To enforce (\textsc{Label} \(a_1, a_2, \ldots\)), we only add in the queue (line [11] in \textsc{ProcessTree}), (tree, edge) pairs where the edge has an allowed label. \textsc{timeout} \(T\) is checked after each newly found rooted tree and within each algorithm’s main loop.

For \textsc{score} \(\sigma\) \([\text{TOP} k]\), the score \(\sigma\) is evaluated either on each new result, or after all results are found, e.g., for the scores in [25], [26]. For any given score \(\sigma\), we may favor (with guarantees, or just heuristically) the early production of higher-score results, by appropriately choosing the priority queue order; this allows search to finish faster. Any order can be chosen in conjunction with MoLESP, since its completeness guarantees are independent of the exploration order.

I. Handling very large seed sets

Our CTP evaluation algorithms build \textsc{init} trees for each seed. This has two risks: (i) when some seed sets are \(N\) (all graph nodes), exploring them may be unfeasible; (ii) one or more seed sets may be very large subsets of \(N\), e.g., orders of magnitude larger than the other seed sets. To handle (i), assuming other seed sets are smaller, we only start exploring (\textsc{init}, \textsc{grow} etc.) from the other (smaller) seed sets; any encountered node is acceptable as a match for the \(N\) seed set(s). To handle (ii), inspired by [7], we use multiple priority
Algorithm 5: Procedure MERGEALL(tree t)

1. toBeMerged ← \{t\};
2. while toBeMerged ≠ ∅ do
3.     currentTrees ← toBeMerged; toBeMerged ← ∅;
4.     for t′ ∈ currentTrees do
5.         mergePartners ← TreesRootedIn(t′.root);
6.         for t_p ∈ mergePartners do
7.             if sat(t′) ∩ sat(t_p) = ∅ and t′ ∩ t_p = \{t′.root\} then
8.                 t′ ← MERGE(t′, t_p);
9.                 if isNEW(t′) then
10.                Add t′ to toBeMerged;
11.           end
12.       end
13. end

It runs in polynomial time in the size of the graph, and by
outperforms DPBF [13]; thus we use QGSTP as a baseline.

an initial result, which it then improves. QGSTP strongly

queues, one for each subset of the seed sets, and GROW at
any point from the queue having the fewest (tree, edge) pairs.
Thus, exploration initially focuses on the neighborhood of the
smaller seed sets, and hopefully encounters INIT trees from
the large seed sets, leading to results.

V. EXPERIMENTAL EVALUATION

We compare CTP evaluation algorithms, then consider sys-
tems capable, to some extent, to evaluate extended queries.

A. Software and hardware setup

We implemented a parser and a query compiler for EQs
(Sec. [I]), and all the CTP evaluation algorithms from Sec. [IV]
in Java 11. Our graphs are stored graph(id, source, edgeLabel,
target) table within PostgreSQL 12.4; we delegate to Postgres
the GP evaluation, and joining the result with CTP trees
(Sec. [I]). When comparing CTP evaluation algorithms with
in-memory competitors, we also load the graph in memory.

We ran our experiments on a server with 2x10-core Intel
Xeon E5-2640 CPUs @ 2.4GHz, with 128-GB DRAM. Every
execution point is averaged over 3 executions.

B. Baselines

Complete CTP evaluation algorithms We use the algorithms
GAM, BFT, BFT-M and BFT-AM as they are the only

Recent, incomplete CTP algorithms To study how our
algorithms compare with incomplete GSTP approximation
(graph keyword search) algorithms, we considered the most
recent ones: QGSTP [13] and LANCET [14], each leveraging
a specific cost function. LANCET relies on DPBF [9] to find
an initial result, which it then improves. QGSTP strongly
outperforms DPBF [13]; thus we use QGSTP as a baseline.

It runs in polynomial time in the size of the graph, and by
design, returns only one result; we used the authors’ code.

Graph query engines Our first two baselines only support
checking, but not returning unbounded-length, unidirectional
paths whose edge labels match a regular expression that
users must provide. Specifically, we use Virtuoso Open-
Source v7.2.6 to evaluate SPARQL 1.1 property path queries.
Internally, Virtuoso translates an incoming SPARQL query
into an SQL dialect (accessible via the built-in function
sparql_to_sql_text(1)) before executing it. Our second
baseline, named Virtuoso-SQL, consists of editing these SQL-
like queries to remove label constraints and thus query the
graph for connectivity between nodes. However, Virtuoso’s

Fig. 7: Synthetic graphs: Comb(3, 1, 2, 3) at the left, Star(4, 2)
at the top right, and Line(3, 1) at the bottom right.

SQL dialect disables returning the nodes and edge labels along
the paths (whereas standard recursive SQL allows it).

Our next three baselines also allow returning paths. JEDI [18]
returns all data paths matching a SPARQL property path; we use the authors’ code. Neo4j supports Cypher queries
asking for all directed or undirected paths between two sets of
nodes. Finally, we used recursive queries in Postgres v12.4
to return the label on paths between node pairs.

C. Datasets and queries

We experiment on real-life as well as synthetic graphs,
aiming to (i) control the parameters impacting the performance
of our algorithms and (ii) compare with our baselines.

To compare CTP evaluation algorithms, we generate three
sets of parameterized graphs and associated CTPs (Fig. 7). The
seeds are labeled A, B, . . . , H; non-seed nodes are labeled 1, 2
each seed set is of size 1. Line(m, nL) contains m seeds, each
connected to the next/previous seed by nL intermediary
nodes, using sL=nL+1 edges. Comb(nA, nS, sL, dB)
consists of a line, from which a lateral segment (called
bristle) exits each seed. There are nA bristles, each made of
nS segments (a segment ends in another seed); each bristle
segment has sL edges, and there are dB nodes in the main
line between two successive bristles. The number of seeds is
m=nA·(nS+1). Star(m, sL) has a central node connected
each of the m seeds by a line of sL edges.

On each Line, Comb, and Star graph, we run a CTP defined by
the m seeds, having 1 result. On Line and Comb, the result
is 2ps (Def. [IV.6]), while on Star, it is a (u, u) rooted merge
(Def. [IV.7]). Thus, by Prop. [9] MoLESP guarantees them.

The Line graphs minimize the number of subtrees for a
given number of edges and seeds: there are O((m·nL)2)
subtrees, and O((m·nL)3) rooted trees. On Star, there are
O(2m·sL2) subtrees, and O(2m·sL3) rooted trees. In Comb
and Line graphs, MoESP trees (Sec. [IV.6]) are part of results.

We also generated Barabasi-Albert (BA) graphs [27] of
200 to 1000 edges. In these graphs, we start with a connected
core of 3 nodes; each extra node adds an edge using preferen-
tial attachment. Seed nodes are chosen at random. As Table III
shows, the random, dense connections of BA graphs yield up
to 20,522 results in a 200-edges graph.

To study the evaluation of our extended query language,
we generate parameterized Connected Dense Forest (CDF)
graphs (see Fig. 5). Each graph has a top forest, and a bottom
forest; each of these is a set of NT complete binary trees of
depth 3. Links connect leaves from the top and bottom forests.
We generate CDFs for mє\{2,3\}: when m=2, chains of edges
connect a top leaf to a bottom one; when m=3, a Y-shaped
connection goes from a top-forest leaf, to two bottom-forest
ones. A CDF graph contains Nf links, each made of Sf edges.
Only top leaves that are targets of “c” edges can participate
to links, and we concentrate the links on 50% of them (the others have no links). When \( m = 2 \), only 50% of the bottom forest leaves that are targets of “g” edges can participate; when \( m = 3 \), 50% of all the bottom forest leaf can participate. The links are uniformly distributed across the eligible leaves.

On CDF graphs with \( m = 2 \), we run the query \( \text{MATCH} (x) \rightarrow \{e_1; c \rightarrow (tl), (v) \rightarrow \{e_2; g \rightarrow (bl), (tl, bl, \{l\}) \} \} \) whose two GPs bind \( tl \), respectively, bl to leaves from the top and bottom forest, while its CTP asks for all the paths between each pair of such leaves. On graphs with \( m = 3 \), we run \( \text{MATCH} (x) \rightarrow \{e_1; c \rightarrow (tl), (v) \rightarrow \{e_2; g \rightarrow (bl_1), (v) \rightarrow \{e_3; h \rightarrow (bl_2), (tl, bl_1, bl_2, \{l\}) \} \} \) requiring connecting trees between \( tl, bl_1 \) and \( bl_2 \). Each CDF query has \( N_L \) results, one for each link. The CDF graphs support both the structured and unstructured parts of our queries, while controlling the number of results.

**Real-world graphs** To compare with JEDI [18] and QGSTP [13], we reused their datasets (a 6M edges subset of YAGO3, and a 18M edges subset of DBPedia), and queries.

**D. CTP evaluation algorithms**

1) **Complete (baseline) algorithms**: We start by comparing the algorithms without any pruning: BFT, GAM, BFT-M and BFT-AM, on Line, Comb and Star graphs of increasing size. We used a TIMEOUT \( T \) of 10 minutes. In all experiments with GAM and all its variants, our exploration order (queue priority) favors the smallest trees, and breaks ties arbitrarily. Fig. 9 depicts the algorithm running time; colors indicate the number of seed sets, while line patterns indicate the algorithm. **Missing points (or curves)** denote algorithms that timed out. Note the logarithmic y axes.

Across these plots, **BFT-M performs worse than BFT-AM**. On Line graphs, the difference is a factor \( 2 \times \) for \( m = 3 \) and up to \( 100 \times \) for \( m = 10 \). On the Comb and Star graphs, BFT-M times out on the larger graphs and queries. **BFT-AM takes even more than BFT-M**, by a factor of \( 15 \times \), thus more executions timed out. **GAM is much faster and completes execution in all cases**. The reason, as explained in Sec. [IV-A] is that breadth-first algorithms waste effort by minimizing results, and may find a tree in even more different ways than GAM, since they grow from any node. Thus, we exclude breadth-first algorithms from the subsequent comparisons.

2) **GAM algorithm variants**: We now compare GAM with our proposed ESP, MoESP, LESP and MoLESP.

Fig. 9 shows the algorithm running times on Line, Comb and Star graphs; in all but Fig. 9d, the y axis is logarithmic.

| \( m \) | \( |E| = 200 \) | \( |E| = 400 \) | \( |E| = 600 \) | \( |E| = 800 \) | \( |E| = 1000 \) |
|---|---|---|---|---|---|
| 2 | 28 | 42 | 42 | 42 | 43 |
| 3 | 833 | 638 | 905 | 778 | 972 |
| 4 | 20522 | 16638 | 15653 | 21473 | 17942 |

**TABLE II**: Number of results in Barabasi-Albert graphs.

On Line and Comb graphs, ESP and LESP failed to find results due to edge set pruning, as explained in Sec. [IV-D] thus the corresponding curves are missing.

The plots show, first, that edge set pruning significantly reduces the running time: **MoESP is faster than GAM by 1.3 \times** (Line graphs) up to \( 15 \times \) (Comb graphs, \( nA = 6, m = 18 \)). Second, on the Star graphs, where LESP (Sec. [IV-F]) applies, the performance difference between MoESP and MoLESP is small. This shows that the extra cost incurred by LESP and MoLESP, which limit or compensate for edge-set pruning (by injecting more trees), is worth paying for the completeness guarantees of MoLESP.

Next, we compare these algorithms on our Barabasi-Albert graphs with \( T = 25 \) minutes. For \( m = 4 \), GAM timed out on even the smallest graph; all our proposed algorithms ran till completion. We report the algorithm running time until the last result is found (\( T_l \)) in Fig. 10a. Fig. 10b shows the number of provenances built by each algorithm (logarithmic y axis). Curves are non-monotonous due to variations in the randomly generated graphs. Fig. 10c plots the algorithm recall (fraction of results found), and Fig. 10d their throughput (results/running time). For \( m = 2 \), all the variants have a full recall (ESP itself is complete, by Prop. [3]). For \( m > 2 \), the incomplete algorithms run faster than MoESP but do not have a perfect recall, thus they also build less provenances. MoESP is at least \( 2 \times \) faster than GAM, with a perfect recall (even for \( m = 4 \), where MoESP may be incomplete), and it builds about \( 5 \times \) less provenances; this shows the interest of MoESP pruning. MoESP has the highest throughput and finds more than 80% of the results; LESP has the lowest throughput with a recall of less than 0.2. For the largest graph, we also plot the number of results found, against the running time, for \( m = 3 \) (Fig. 10e) and \( m = 4 \) (Fig. 10f). MoESP finds the results in about half the time as GAM; for the initial results, it closely follows MoESP. LESP takes longer in order to find its (incomplete) results. MoESP has the advantage of MoESP and thus, a higher throughput and faster result finding than GAM; it is also pulled-down by LESP which is essential in order to guarantee completeness. Overall, **MoESP is the best complete algorithm; among the incomplete ones, MoESP has the best throughput and recall**.

3) **Comparison with QGSTP on real-world data**: We now compare our best algorithm, MoESP, with GAM and QGSTP [13] on the 18M edges DBPedia dataset and 312 CTPs used in their evaluation. Among these, 83 CTPs (respectively, 98, 85, 38, 8) have 2 (respectively, 3, 4, 5, 6) seed sets. To align with QGSTP, we added a UNI restrictor (unidirectional exploration only), and ANY 1 selector to find just one result. Each QGSTP returned result is such that Prop. [9] ensures MoESP finds it. Fig. 11a shows the average runtimes grouped by \( m \). GAM is faster than QGSTP for \( m \leq 5 \), but
timed-out for the 8 CTPs with m=6. MoLESP is about 6-7× faster than QGSTP for all m values, and scales well as m increases. Thus, MoLESP is **competitive also on large real-world graphs and queries**.

**E. Extended query (EQ) evaluation**

1) Synthetic queries on CDF benchmark: We now compare our EQ evaluation system with the closest graph query evaluation baselines, on our CDF graphs (Sec. V-C) generated with m∈{2,3}, S_L∈{3,6}, 18K to 2.4M edges, leading to 2K up to 200K results (N_L), respectively. We used T=15 minutes. As explained in Sec. III the paths returned by the baselines, which we stitch for m=3, semantically differ from CTP results; the baselines’ reported time do not include the time to minimize nor deduplicate their results.

For m=2, Fig. [1b] shows that all systems scale linearly in the input size (note the logarithmic time axis). For each system, the lower curve is on graphs with S_L=3, while the upper curve is on graphs with S_L=6 (these curves go farther at right). All missing points correspond to time-out. JEDI succeeded only on the smallest graph, Neo4j timed-out on all. Virtuoso-SPARQL is the fastest, closely followed by Virtuoso-SQL; they are both unidirectional, require the edge labels, and do not return paths. Unidirectional MoLESP is slower by approximately 3× only. JEDI is slower than MoLESP by 10^3× on the smallest graph, and timed-out on the others. Postgres is faster than JEDI, yet at least 10× slower than MoLESP. MoLESP is the only feasible bidirectional algorithm; it completes in less than 2 minutes on the largest graph with 2.4M edges.
TABLE III: Query evaluation times (seconds) on YAGO3.

![Graph](image-url)

Fig. 11: Comparison with state-of-the-art systems.

Fig. 11c shows similar results for m=3. Postgres timed-out in all cases. Virtuoso-SPARQL is 7× faster than Virtuoso-SQL; both return non-minimal, duplicate results. UNI-MoLESP outperforms every system. Note that the bidirectional MoLESP found about 7× more results than the N_L expected ones, by also connecting bottom leaves without a common parent through their grandparent node; these results are filtered by the join between the GPs and the CTP (Sec. [I]).

Despite the much larger search space due to bidirectionality, MoLESP scales well with the size of the graph and the cost of adding CTP to graph query engines is minimal.

2) Comparison with JEDI on real-world data: JEDI [18] used a set of (unidirectional, label-constrained) SPARQL 1.1 queries over YAGO3. Table III shows the queries’ characteristics. We compare MoLESP similarly restricted (UNI and LABEL), on these queries, with JEDI, Virtuoso and Neo4j (Postgres timed-out on all). Query J2 has one very large seed set, while query J3 has a N seed set. On queries J2 and J3, MoLESP timed out. Thus, we applied the optimizations described in Sec. [IV] which enabled it to perform as shown. Virtuoso-SPARQL completed query J1, then ran out of memory. Compared with JEDI, our query evaluation engine is 2× faster on J1, close on J2, and around 3× slower on J3. MoLESP took around 30% of the total time, the rest being spent by Postgres in the GP evaluation and final joins.

This shows that the optimizations described in Sec. [IV] make MoLESP robust also to large seed sets.

VI. RELATED WORK

We focused on integrating connecting tree patterns (CTPs) into GPML [1], for which no parser or implementation is yet available [28]. Searching for connecting trees is not currently supported in any graph language. As outlined in Sec. [III] languages such as SPARQL allow checking for paths connecting given nodes, but not returning them; others, including G-CORE [19], GPML, and Neo4j’s Cypher return paths, however, the latter does not scale (Sec. [V]). RPQProv [29] uses recursive SQL to return path labels; JEDI [18], [30] returns unidirectional paths (only). Many works focus on finding label-constrained paths between nodes [31]–[45], typically by using precomputed indexes or sketches. In our CTP evaluation algorithm, an index could be integrated by “reading from it” subtrees on which to GROW and MERGE. Going beyond paths, CTPs find trees connecting an arbitrary number of seed sets (m≥3), traversing edges in any direction, independent of a scoring function; we guarantee completeness for m≤3 and finding a large set of results for arbitrary m. Path stitching leads to different results, which may require deduplication and minimization (Sec. [III]).

CTP evaluation is directly related to keyword search in (semi-)structured data; good surveys are [11], [12], [46]. The prior studies differ from ours: (i) [10], [47]–[55] assume available a compact summary of the graph; (ii) [54], [56]–[58] assume a compact summary of the graph; (iii) [7], [9], [23], [59] depend heavily on their score functions for pruning the search, particularly to approximate the best result [9], [59], [60] or return only top-K results [5], [8], [23]. [49], [61]; (iv) [5], [9], [10], [23], [47], [62] are only unidirectional. For these reasons, they fail to meet our requirements (R2) to (R5) as outlined in Sec. [I]. MoLESP brings new, orthogonal, optimizations, and novel guarantees to the multi-threaded, C++ version [4] of GAM.

VII. CONCLUSIONS

We introduced CTPs, a new primitive for unstructured search in graphs, and showed how to integrate it within a graph query language such as GPML. We proposed novel algorithms which enumerate CTP results fully independently of a score function used to rank the CTP result trees. Some of our algorithms are guaranteed to find all results, but risk a high computational cost; others guarantee all results for at most 3 seed sets, or all results of certain shapes. MoLESP has the best trade-off between completeness and efficiency; our evaluation against the state-of-the-art systems demonstrates its performance. As part of our future work, we optimise the evaluation of multiple (batched) CTPs by sharing computations.

An intrinsic limitation of CTP (and EQ) evaluation is the potential search space explosion, when allowing edges in any direction, and/or when querying large, highly connected graphs. In such cases, depending on the user needs, a search method guaranteeing some answers, qualified wrt a specific cost metric, e.g., [13], [14], could be preferred.
