Disentanglement is a run-time property of parallel programs that facilitates task-local reasoning about the memory footprint of parallel tasks. In particular, it ensures that a task does not access any memory locations allocated by another concurrently executing task. Disentanglement can be exploited, for example, to implement a high-performance parallel memory manager, such as in the MPL (MaPLe) compiler for Parallel ML. Prior research on disentanglement has focused on the design of optimizations, either trusting the programmer to provide a disentangled program or relying on runtime instrumentation for detecting and managing entanglement. This paper provides the first static approach to verify that a program is disentangled: it contributes DisLog, a concurrent separation logic for disentanglement. DisLog enriches concurrent separation logic with the notions necessary for reasoning about the fork-join structure of parallel programs, allowing the verification that memory accesses are effectively disentangled. A large class of programs, including race-free programs, exhibit memory access patterns that are disentangled "by construction". To reason about these patterns, the paper distills from DisLog an almost standard concurrent separation logic, called DisLog+. In this high-level logic, no specific reasoning about memory accesses is needed: functional correctness proofs entail disentanglement. The paper illustrates the use of DisLog and DisLog+ on a range of case studies, including two different implementations of parallel deduplication via concurrent hashing. All our results are mechanized in the Coq proof assistant using Iris.

CCS Concepts:
- Software and its engineering → Parallel programming languages;
- Theory of computation → Separation logic; Program verification.

Additional Key Words and Phrases: disentanglement, parallelism, separation logic

ACM Reference Format:

1 INTRODUCTION
Recent work has shown that parallel functional programming can deliver the same efficiency and scalability as imperative and procedural approaches. The key to this line of work is a memory property known as disentanglement [Arora et al. 2021, 2023; Guatto et al. 2018; Raghunathan et al. 2016; Westrick et al. 2022, 2020], which restricts parallel tasks to access data that was allocated “before” the task executed. This restriction enables tasks to allocate and garbage-collect memory locally and independently—that is, without synchronizing with other parallel tasks. Utilizing disentanglement, Arora et al. [2023] developed a provably efficient memory manager for functional programs which also provides full support for effects. All of this work is implemented in MPL.
("maple"), an open-source\textsuperscript{1} compiler for Parallel ML. In practice, MPL has been shown to be fast, scalable, and competitive with lower-level and imperative language implementations.

This line of work relies on disentanglement to ensure efficiency and scalability, and leaves it up to the programmer to reason about disentanglement and its performance impact. For purely functional code, reasoning about disentanglement is not an issue: purely functional programs are guaranteed to be disentangled, by construction, due to the lack of mutation (in-place updates). Programmers can also use pure libraries that are implemented under-the-hood with in-place updates for efficiency. For example, common parallel operations (such as \texttt{map}, \texttt{reduce}, \texttt{scan}, etc.) can be implemented efficiently with mutable arrays, hidden behind a pure interface, and can then be used to write disentangled code. However, in this example, the developers of high-performance libraries still need to reason carefully about disentanglement. More generally, whenever in-place updates and other low-level optimizations are necessary for efficiency, disentanglement needs to be taken into account.

In the context of in-place updates and other memory effects, reasoning about disentanglement is subtle. Programmers may wish to use concurrent data structures (for example, lock-free hash tables) to improve efficiency. Such data structures can be made disentangled \cite{Westrick2022}, but reasoning about their correctness is challenging, even for experts. If disentanglement is violated, there can be significant consequences for performance, in terms of increased time and space usage \cite{Arora2023}. In this sense, disentanglement can be considered a "safety" condition for performance-oriented code.

Therefore, we shift our attention to static verification of disentanglement. Our goal is to support reasoning about both high-level and low-level code, including atomic in-place updates and concurrent data structures, which can require identifying intricate invariants. In this setting, concurrent separation logic \cite{Brookes2007, O'Hearn2007} and its modern variants \cite{Jung2018, Nanevski2014} have proven to be successful vehicles for verifying safety and correctness properties of programs in the presence of challenging concurrent features. An intriguing question is whether or not separation logic can be used to prove disentanglement, which we address in this paper.

To verify disentanglement statically, we develop \textbf{DisLog}, the first program logic for proving disentanglement, and formally prove its soundness. At a high level, DisLog is a concurrent separation logic built on Iris \cite{Jung2018} endowed with assertions which describe dependencies between parallel tasks and permissions to make disentangled loads from the heap. This approach makes the logic powerful enough to verify disentanglement even in complex and subtle situations, such as programs with lock-free data structures and algorithms using atomic in-place reads and writes.

Going further, on top of DisLog, we develop \textbf{DisLog+}, a standard concurrent separation logic which hides the details of disentanglement, allowing for standard separation logic proofs while also getting proofs of disentanglement for free. DisLog+ is applicable for a wide variety of programs, including purely functional programs, race-free programs, and even programs that have "benign" memory races (for example, write-write races). Importantly, DisLog and DisLog+ work seamlessly together, allowing for DisLog+ proofs to drop into the more powerful DisLog where needed (for example, for verifying non-pure segments of mostly pure programs), and otherwise stay at a high level of abstraction.

To evaluate DisLog and DisLog+, we consider several case studies, including key parallel primitives, as well as sophisticated parallel algorithms involving concurrent data structures. In all cases, we prove that the programs are disentangled. Our experience has shown that, using the logics developed in this paper, the effort of proving disentanglement is typically small. Furthermore, when a formal proof of functional correctness is desired, using DisLog+ often yields a proof of disentanglement for free.

\textsuperscript{1}https://github.com/mpllang/mpl
Our contributions include:

- **DisLog**, the first program logic to verify that a program is disentangled (§4). It employs the notion of *timestamps* to reason about the nested fork-join parallelism of a program and introduces a novel *clock* assertion to prove that memory accesses do not cause entanglement.

- **DisLog+,** a high-level logic built on top of DisLog that shields the user from timestamp management (§5). As a result, race-free programs can be verified in DisLog+ with the standard reasoning rules of concurrent separation logic.

- Two mechanisms allowing to reason about benign races in DisLog+, including fractional write-only assertions for write-write races (§5.4), and a set of rules for read-write races on pre-allocated data (§5.5).

- A range of case studies (§6), including multiple parallel primitives, parallel lookup in a lazy collection, and two examples of deduplication via concurrent hashing.

- A formalization in the Coq proof assistant using Iris [Jung et al. 2018]. All our results are mechanized (§7) in Coq, including: the two program logics, their soundness theorems, and the case studies [Moine et al. 2023b].

2 KEY IDEAS

2.1 Background

*Nested Fork-Join Parallelism.* We consider programs written using a single parallel primitive: the parallel tuple $e_1 || e_2$. It executes $e_1$ and $e_2$ in parallel, and returns their results as a pair. Here, two *tasks* are spawned to execute expressions $e_1$ and $e_2$ in parallel. Parallel tuples may be arbitrarily nested. For example, the expression $e_1$ might itself execute another parallel tuple. This leads to a dynamic nesting structure of tasks called the *task tree*, where the leaves are tasks that may take steps in parallel. In an operational semantics, the task tree is maintained by two distinguished reductions: a *fork*, where two tasks are spawned to execute $e_1$ and $e_2$ in parallel, and a *join*, when the tasks complete and return their results as a pair. Parallel tasks can be understood as concurrent threads *with a structure*: if they terminate, the two tasks forked by a parallel pair ultimately join.

This style of programming is known as *nested fork-join parallelism*, or sometimes *nested task parallelism*. The arbitrary nesting of parallel tasks allows programmers to write parallel recursive divide-and-conquer style algorithms. For example, a “parallel for-loop” can be implemented by splitting the index range in half and then recursively executing the two halves in parallel (§6.2).

*Acquiring locations.* During execution, each task may allocate locations in memory and perform memory effects such as reads and writes on these locations, including atomic compare-and-swaps (CAS). The reads in particular are important for the disentanglement property we consider. In our operational semantics (§3.3), a read occurs in three distinct cases: (1) a memory load inside an array reads the indexed value, (2) a closure call reads the environment of the closure, and (3) a CAS reads the scrutinized value. When a task performs a read, if the result of that read is a location, we say that the task *acquires* the resulting location.

*Disentanglement.* Disentanglement limits communication between concurrent tasks by restricting which locations may be acquired: each task may always acquire its own allocations, and additionally, each task may acquire any location allocated “before” the task began. The notion of “before” relates to the dependencies induced by forks and joins. A forking task comes before the two tasks it forks, and conversely, two joining tasks come before their join point. If a task ever acquires a location allocated by some other task that is executing concurrently, this constitutes *entanglement*. The logics developed in this paper allow proving that a program is disentangled, i.e., that in every possible execution of the program, entanglement will never occur.
Atomic operations and determinacy races. A key feature of disentanglement is that it allows for non-deterministic interleaving of atomic in-place operations such as atomic loads, stores, and CASes. Such operations are commonly used under-the-hood in the implementation of high-performance libraries (for example, in the implementation of a high-throughput lock-free hash table). Proving disentanglement in this setting requires reasoning carefully about atomic operations that can acquire locations.

In other words, one of the challenges is to prove that entanglement is impossible whenever there is a determinacy race [Feng and Leiserson 1999]. Concretely, a determinacy race occurs whenever two atomic in-place operations are performed concurrently at the same location, and at least one of the operations modifies the location. For example, an atomic load could race with an atomic store, or an atomic load could race with a CAS, or two CASes could race with each other, etc. As the name suggests, determinacy races can lead to non-deterministic execution, which we allow.

In this paper, we permit only atomic (i.e., properly synchronized) in-place operations, and therefore avoid all data races [Adve 2010; Boehm 2011; Dolan et al. 2018] by construction. For simplicity, we assume a sequentially consistent memory model. Because of the lack of data races, throughout the paper, we use the term race to refer only to determinacy races.

2.2 Running Example

To illustrate the ideas in the paper, we use a running example, called scratch, shown in Fig. 1. This function is non-deterministic due to a determinacy race, yet is disentangled. At a high level, scratch calls the function doWork two times in parallel. Each call to doWork uses an array (called a “scratchpad”) as temporary space. Note that it would be safe to allocate a fresh scratchpad for every call to doWork. The goal of the example is to optimize performance by reducing the number of scratchpads that are allocated. (The example only calls doWork twice, but this could be generalized to any number of calls in parallel, which would make the optimization more significant.)

To reduce the number of allocated scratchpads, scratch implements a simple strategy. First, a shared scratchpad is allocated together with a lock to protect it (Fig. 1, lines 3–5). Then, before

```plaintext
fun scratch () = 
let 
val shared = newScratchpad() 
val {tryLock, releaseLock} = newLock() 
fun myTask () = 
if tryLock () then 
(doWork shared; 
clearScratchpad shared; 
releaseLock()) 
else 
let val 𝑥 = newScratchpad () 
in doWork 𝑥 
in // two calls in parallel (could be 
// generalized to many calls if desired) 
(myTask () || myTask ())

(a) The scratch function calls doWork multiple times in parallel, and provides a suitable scratchpad for each call.

(b) Auxiliary code for scratch, including locks, scratchpads, and a function doWork that requires a scratchpad as temporary space.
```

Fig. 1. The scratch example used to illustrate our approach.
each call to `doWork`, `scratch` will attempt to claim access to the shared scratchpad by calling `tryLock` (line 7). If this succeeds, then `doWork` may use the shared scratchpad (line 8); otherwise, `scratch` falls back on allocating a fresh scratchpad (line 12). Whenever a call to `doWork` is finished using the shared scratchpad, the shared scratchpad is cleared (line 9), before finally releasing the lock (line 10). In this way, `scratch` reduces the number of allocations by reusing the shared scratchpad as much as possible. In particular, if `scratch` is executed using only a single processor, then every call to `doWork` will be able to use the shared scratchpad, and no additional scratchpads will be allocated.

The auxiliary code for the example is shown in Fig. 1b, which defines scratchpads and locks. The details of `doWork` are not important as long as it performs reads and writes on the scratchpad. Locks are implemented by a pair of closures with a mutable boolean, indicating whether the lock has been locked. The closure `tryLock` is implemented using an atomic compare-and-swap (CAS) which returns `true` if the CAS succeeds, and `false` otherwise.

Disentanglement in `scratch`. Proving that the `scratch` example is disentangled is subtle. In particular, `doWork` may read or write to the scratchpad, and we need to show that reading from the scratchpad will never return a value allocated by a concurrent task. Thankfully, the `scratch` function guarantees a strong precondition: when `doWork` begins, the argument `scratchpad` will contain only the value `defaultElem`, which is allocated before every call to `doWork`, and therefore is safe with respect to disentanglement.

The precondition on `doWork` is easily satisfied on line 13, because the scratchpad is freshly allocated. Showing that the precondition is also satisfied on line 8 is more subtle, because there is an invariant on the shared scratchpad which is determined by the state of the lock. Informally, the invariant is: “while the lock is not held, for every i, shared[i] = defaultElem.” This invariant is re-established by calling `clearScratchpad` (line 9) before releasing the lock. Note that removing this call to `clearScratchpad` may lead to an entangled state. Indeed, after a call to `doWork`, the scratchpad may contain locally-allocated data, which is hence available for the other task.

2.3 Disentanglement: Timestamps, Reads, and How to Reason about Them

Partial orders on tasks through timestamps. In Sec. 3, we present a semantics that facilitates reasoning about disentanglement. To this end, we enrich the semantics with the notion of a timestamp, a unique identifier for each parallel task. We then assign every heap-allocated location
a timestamp, marking when (i.e., by which task) the location was allocated, and restrict every task to only depend on locations allocated at timestamps that come before their timestamp. Timestamps form a partial order which respects the dependencies induced by forks and joins. When a task forks, the semantics generates two timestamps (one for each task) that are preceded by the timestamp of the forking task. Conversely, when two tasks join, the semantics generates a timestamp that is preceded by both timestamps of the two joining tasks. Forks and joins are the only operations extending the partial order of timestamps. Tasks otherwise step independently.

Fig. 2 visualizes one possible execution of the running example. Each shaded oval represents a task, and is labeled by its timestamp $t_i$. The framed content is not relevant yet. Execution begins on a task $t_1$, which allocates the scratchpad and the lock. Then, a fork occurs, generating two tasks $t_2$ and $t_3$. The task $t_2$ fails to win the lock, whereas the task $t_3$ succeeds. After completing, the two tasks join, forming a new task $t_4$.

A program logic for timestamp orders. In Sec. 4, we develop a program logic, DisLog, that incorporates timestamps. Every expression in DisLog is associated with a current timestamp and an end timestamp. The program logic uses a weakest precondition (WP) modality which takes the form

$$\text{wp} \langle t, e \rangle \{ \lambda t'. v. \Phi \}$$

asserting that the expression $e$ is currently evaluated by a task at timestamp $t$, that $e$ is disentangled and can reduce, and if its reduction terminates, then it does so at end timestamp $t'$, yielding a value $v$ such that $\Phi$ holds. The partial order of timestamps is encoded into the assertions of the logic, via the precedence assertion $t \preceq t'$. The precedence assertion is persistent and hence duplicable at will. This assertion describes the parallel structure of the program being verified.

Examples of the precedence assertion $t \preceq t'$ appear in the framed boxes of Fig. 2. To reason about the task $t_2$, the user gets an assertion $t_1 \preceq t_2$. Dually, the user gets an assertion $t_1 \preceq t_3$ to reason about the task $t_3$. At the join point $t_4$, the user gets the assertions $t_2 \preceq t_4$ and $t_3 \preceq t_4$. Making use of the fact the $\preceq$ is a pre-order, the user can use transitivity and deduce for example that $t_1 \preceq t_4$.

Preserving disentanglement. Acquiring a memory location $\ell$ from the heap puts disentanglement at risk. Disentanglement is preserved if and only if $\ell$ was allocated at some timestamp preceding the timestamp $t$ of the acquiring task—in that case, we say that $\ell$ was allocated before $t$. To represent such a requirement, we introduce the clock assertion, written $\ell \odot t$, which precisely asserts that the $\ell$ was allocated before $t$. This assertion appears for example in the precondition of DisLog’s LOAD rule (§4.3). To illustrate this rule, we show a specialized instantiation allowing to load the element at index 0 in the shared scratchpad, here named $\ell$. The premises are implicitly separated by the separating conjunction $\ast$.

$$\text{SpecializedLoad} \quad \text{shared} \leftrightarrow [\ell; \ldots] \quad \ell \odot t$$

$$\text{wp} \langle t, \text{shared}[0] \rangle \{ \lambda t'. v. \Phi' = t \land v = t \ast \text{shared} \leftrightarrow [\ell; \ldots] \}$$

The SpecializedLoad rule first requires, as in standard separation logic, ownership of the shared location via a points-to assertion. Crucially, this rule also requires that the loaded value $\ell$ was allocated before the current timestamp $t$ via the $\ell \odot t$ assertion. In the postcondition of the WP, the rule asserts that the end timestamp $t'$ is equal to the previous timestamp $t$, the returned value $v$ is $\ell$, and the user still has the points-to ownership.

The clock assertion is persistent, giving the user great flexibility. Moreover, it is monotonic with respect to the precedence pre-order. Hence, if the user knows that the location $\ell$ was allocated before $t$ and that $t$ precedes $t'$ they can then deduce that $\ell$ was allocated before $t'$. This mechanism is illustrated in Fig. 2. Indeed, the user can produce an assertion $\text{defaultElem} \odot t_1$ upon the allocation of defaultElem. Then, while reasoning about $t_5$ the user can use the assertion $t_1 \preceq t_5$ to generate
a new clock assertion $\text{defaultElem} \oplus t_3$. As explained next, our high-level logic DisLog+ takes full advantage of the monotonicity of the clock assertion.

2.4 Going High-Level: Simple Programs Should Have Simple Proofs

Readers familiar with proofs of realistic programs may be worried by timestamps polluting the logic, and the additional proof burden imposed on a common rule such as LOAD. In practice, many programs “don’t poke the bear” and subtle reasoning about timestamps should not be needed. For example, Westrick et al. [2020] show that race-free programs are always disentangled, as they prevent the communication of concurrently-allocated locations. Verifying such programs should be as cheap as a standard separation logic proof.

In Sec. 5, we present DisLog+, a high-level separation logic where timestamps, clocks, and precedence are confined to very few occurrences. DisLog+ allows reasoning on race-free programs with the standard reasoning rules of concurrent separation logic. The sole difference is a restriction on ghost state, effectively preventing races (§5.3). What is the secret of the DisLog+ logic? The key observation we make on race-free programs is that (1) the content of a freshly allocated location is always safe to acquire for the allocating task and (2) “being safe to acquire” is a monotonic property: if a location is safe to acquire for a given task, it is safe to acquire for every subsequent task. As long as a program does not write carelessly to a shared location and break monotonicity, locations are always safe to acquire and no reasoning about timestamps is needed.

Technically, we define assertions of DisLog+ as monotonic predicates of DisLog over an ambient timestamp, the latter being implicitly threaded through during the proof. Points-to assertions of DisLog+ store not only ownership information but also the proof that all pointed-to locations are safe to acquire at the ambient timestamp. Hence, DisLog+ provides a standard LOAD reasoning rule. We stress that DisLog+ is a light abstraction over DisLog. At any moment during the proof, the user of DisLog+ can fall back to DisLog for fine timestamp-related reasoning.

Our definition of DisLog+ is directly inspired by separation logics for weak-memory models: iGPS [Kaiser et al. 2017], iRC11 [Dang et al. 2020] and Cosmo [Mével et al. 2020]. These high-level logics are defined in terms of low-level logics by implicitly threading through a monotonic view of the memory.

**Beyond race freedom.** It turns out that DisLog+ is not confined to reasoning about race-free programs, but additionally provides two new sets of high-level reasoning rules to accommodate the most elementary disentangled races. The first one consists of fractional write-only assertions (§5.4) allowing the user to reason about write-write races within DisLog+. As a write-write race does not acquire any location, such a race is always disentangled. The second one consists of a set of rules unveiling just enough timestamps to reason about races on “obviously safe” data (§5.5). These data include data that was allocated before the beginning of the parallel phase, and unboxed data—that is, data that is not allocated in the heap.

The language we model supports the atomic operation compare-and-swap (CAS). A CAS is an entanglement hazard. Indeed, a CAS reads the scrutinized value, which must be safe to acquire. In the scratch running example (Fig. 1b), we use CAS to implement a spin-lock. Here, we exploit unboxed data to allow parallel tasks to safely communicate via a race on shared reference $r$. A “race on unboxed data” should ring a bell: it perfectly fits in the realm of DisLog+ and its extensions. We show in Sec. 6 how to reason about our locks and scratch entirely within the high-level DisLog+.

3 LANGUAGE AND SEMANTICS

Our language, DisLang, is an imperative lambda-calculus with fork-join parallelism. We equip DisLang with a small-step, substitution-based, call-by-value semantics, guaranteeing disentanglement.
The dynamics of DisLang, presented in the next section, makes use of a computation graph, capturing the nested fork-join parallel structure of a program. A computation graph is a directed acyclic graph where vertices, or tasks, represent sequential computations, and edges represent the dependencies between them [Acar et al. 2016]. We label each task with a unique timestamp \( t \), from an infinite set \( \mathcal{T} \). When a task \( t_0 \) forks two fresh tasks \( t_1 \) and \( t_2 \), the computation graph is extended with edges \( \langle t_0, t_1 \rangle \) and \( \langle t_0, t_2 \rangle \). Conversely, when two completed tasks \( t_1 \) and \( t_2 \) join to form a fresh task \( t_3 \) the computation graph is extended with edges \( \langle t_1, t_3 \rangle \) and \( \langle t_2, t_3 \rangle \). As discussed earlier, an example computation graph for the scratch example (§2) is shown in Fig. 2.

In a computation graph \( G \), we say that \( t \) precedes \( t' \) and write \( t \prec_G t' \) when there exists a sequence of edges in \( G \) from \( t \) to \( t' \). In particular, we say that two tasks are concurrent when neither precedes the other. Entanglement occurs when a task acquires a location that was allocated by a concurrent task. Recall our running example (§2, Fig. 1): a particular implementation of \texttt{doWork} can store a locally_allocated_location in the shared scratchpad. If it were possible for two concurrent tasks to both win the lock, without proper cleaning of the scratchpad, this locally_allocated_location could be acquired by the concurrent task, generating entanglement.

\text{HeadCASFail} & \quad \sigma(\ell) = \nu \quad 0 \leq i < |\nu| \\
G, t & \vdash \sigma \backslash \alpha \backslash \ell \leftarrow v \quad \rightarrow \quad [\ell := [i := v']\nu]\sigma \backslash \alpha \backslash \text{false} \\
\end{align*}
\]

Fig. 4. Head reduction. The disentanglement proof obligation is highlighted.

### 3.3 Operational Semantics

**Head Reduction.** Fig. 4 defines the head reduction relation \( G, t \vdash \sigma \backslash \alpha \backslash e \rightarrow \sigma' \backslash \alpha' \backslash e' \) between two \textit{head configurations} \( \sigma \backslash \alpha \backslash e \) and \( \sigma' \backslash \alpha' \backslash e' \), where \( G \) is the (global) computation graph and \( t \) the timestamp of the (local) task at which the reduction takes place. A head configuration consists of the expression \( e \) being evaluated, the \textit{store} \( \sigma \), and an \textit{allocation map} \( \alpha \). A store \( \sigma \) is a finite map of locations to blocks, representing the heap, and an allocation map \( \alpha \) is a finite map of locations to timestamps, recording the timestamps at which locations were allocated.

We write \( \sigma(\ell) \) to denote the block stored at the location \( \ell \) in the store \( \sigma \). To insert a block into the store or update the store, we write \( [\ell := r]\sigma \). Note that only arrays can be updated; closures are immutable. To refer to the index \( i \) of an array \( \nu \), we write \( \nu(i) \), and to update an array, we write \( [i := v]\nu \). We similarly write \( [\ell := t]\alpha \) for an insertion in the allocation map. We write \( \nu^0 \) for an array of length \( n \), where each element of the array is initialized with the value \( v \).

The \texttt{HeadAlloc} and \texttt{HeadClosure} reductions allocate heap blocks, arrays and closures, respectively, extending the store with the desired block and the allocation map with the current timestamp. The \texttt{HeadCallPrim} reduction encompasses a reduction \texttt{pure} to compute a primitive operation. The \texttt{HeadStore} reduction updates the field of an array, and the \texttt{HeadLength} reduction returns the length of an array. The \texttt{HeadLetVal} reduction substitutes a variable by its value. The \texttt{HeadIfTrue} and \texttt{HeadIfFalse} reductions reduce an if-then-else construction where the conditional is evaluated.

Entanglement may only occur when a task acquires a location. Locations are acquired during the reductions \texttt{HeadLoad}, \texttt{HeadCall}, \texttt{HeadCASSucc} and \texttt{HeadCASFail}. A load reads the indexed value, a call the environment of the closure, and a CAS the scrutinized value.
The main reduction relation

\[ S \vdash (\sigma, \alpha, G) \]

\[ (\sigma, \alpha, G) \] consists of the tuple \((\sigma, \alpha, G)\), denoting a store \(\sigma\), an allocation map \(\alpha\), and a computation graph \(G\). The \texttt{StepParl} reduction describes a scheduling step. The other reductions

---

**Fig. 5. Reduction under a context and parallelism**

Parallelism and Reduction under a Context. To keep track of the currently active and suspended tasks of an executing parallel program, we follow Westrick et al. [2020] and enrich the semantics with an auxiliary structure called a task tree, written \(T\), of the following formal grammar:

\[ T \triangleq t \in T \mid T \otimes T. \]

A leaf represents an active task and is denoted by its timestamp \(t\). A node \(T_1 \otimes T_2\) represents a suspended task that has forked two parallel computations, recursively described by the task trees \(T_1\) and \(T_2\).

Taking advantage of task trees, we define the semantics of parallel reductions and reductions under a context in Fig. 5. We define a scheduling reduction \(\sigma / \alpha / G / T / e \overset{\text{sched}}{\rightarrow} \sigma' / \alpha' / G' / T' / e'\) as either a head step, a fork, or a join. In this reduction relation, \(\sigma\) is a store, \(\alpha\) an allocation map, \(G\) a computation graph, \(T\) a task tree, and \(e\) an expression. The \texttt{SchedHead} reduction describes a head reduction. The \texttt{SchedFork} reduction describes a fork: the task tree is at a leaf \(t_0\) and faces a parallel tuple. The reduction generates two fresh timestamps \(t_1\) and \(t_2\), adds the corresponding edges to the computation graph and updates the task tree to the node with two leaves \(t_1 \otimes t_2\). The \texttt{SchedJoin} reduction describes a join: the task tree is at a node with two leaves \(t_1 \otimes t_2\), and both leaves reached a value. The reduction generates a fresh timestamp \(t_3\), updates the computation graph, and allocates a memory cell to store the result of the parallel tuple. It then updates the task tree to the leaf \(t_3\).

The main reduction relation \(S / T / e \overset{\text{step}}{\rightarrow} S' / T' / e'\) describes a scheduling reduction inside the whole parallel program. A tuple \(S / T / e\) consists of the program state \(S\), the task tree \(T\), and an expression \(e\). A state \(S\) consists of the tuple \((\sigma, \alpha, G)\), denoting a store \(\sigma\), an allocation map \(\alpha\), and a computation graph \(G\). The \texttt{StepSched} reduction describes a scheduling step. The other reductions
describe where the scheduling reduction takes place. The StepBind reduction describes a reduction under an evaluation context. The StepParL and StepParR reductions unveil the non-determinism of the parallel reduction. If a node of the task tree is encountered facing a parallel tuple, the left side or the right side can reduce.

4 DISLOG, A PROGRAM LOGIC FOR DISENTANGLEMENT

In this section, we present the details of DisLog. We first give an Iris primer and explain our notations (§4.1). Then, we showcase how timestamps appear in the program logic (§4.2), and present other reasoning rules (§4.3). Finally, we discuss the soundness theorem of DisLog (§4.4).

4.1 Assertions and Weakest Preconditions

We build DisLog on top of Iris [Jung et al. 2018], adopting Iris’ syntax. In particular, we write \( ⟨\wp t, e⟩\{λ t’ v. Φ⟩ \)

This modality adapts a standard Iris’ WP to the semantics of DisLang, and in particular, enriches it to account for timestamps. In the above assertion, \( t \) is the timestamp of the task which symbolically executes the expression \( e \). We call this timestamp the current timestamp of the expression. A postcondition takes the form \( λ t’ v. Φ \) where the variables \( t’ \) and \( v \) are bound in \( Φ \). The variable \( v \) denotes the resulting value and the variable \( t’ \) the end timestamp, the timestamp of the returning task. We write \( \wp ⟨t, e⟩\{λ t’ ℓ. Φ⟩ \), where the variable \( ℓ \) denotes a location, as a syntactic sugar for \( \wp ⟨t, e⟩\{λ t’ v. ∃ ℓ. r e = ℓ v * Φ⟩ \). We similarly do so for booleans \( b \) and integers \( i \). If we want to abstract over the details of the postcondition, we write \( Ψ \) instead of \( λ t’ v. Φ \).

Our WP is subject to the standard structural rules of separation logic. DisLog supports in particular the Frame rule that we present below, as a warm-up to our notations. We write reasoning rules as inference rules, where premises are separated by the separating conjunction \( * \) and entail the conclusion. In particular, if the conclusion is a WP, premises amount to preconditions.

\[
\frac{Φ₀ \quad \wp ⟨t, e⟩\{λ t’ v. Φ₁⟩}{\wp ⟨t, e⟩\{λ t’ v. Φ₀ * Φ₁⟩}
\]

Separation logic triples can be obtained with the standard definition \( \{Φ⟩ ⟨t, e⟩\{Ψ⟩ \overset{≡}{=} □(Φ * \wp ⟨t, e⟩\{Ψ⟩) \), where \( □ \) stands for the persistence modality of Iris. The persistence modality characterize persistent assertions (an assertion \( Φ \) is persistent when \( Φ * □ Φ \)). Once a persistent assertion holds, it holds forever. In particular, persistent assertions are duplicable.

Iris features ghost state, which is hence available in DisLog. We write \( Φ ⇒ Φ' \) for a ghost update (or fancy update) that updates the ghost state. We omit the so-called masks for the sake of readability. Thanks to the ghost state, DisLog supports Iris invariants [Jung et al. 2018, §2.2], with a standard interface. Our WP allows the user to assume (or open) an invariant before reasoning about an atomic expression and generates an obligation to restore (or close) the invariant in the postcondition. An atomic expression is an expression that can reduce to a value in a single head step of computation. We syntactically characterize such assertions with the Atomic e pure predicate.

DisLog makes use of fractional [Bornat et al. 2005; Boyland 2003] and discardable [Vindum and Birkedal 2021] points-to assertions of the form \( ℓ ⊢→_p \tilde{w}, \) where \( p \) denotes either a positive fraction less than or equal to 1, or a discarded fraction written \( □ \). The latter makes the points-to assertion
null
### 4.3 Reasoning Rules for Expressions

Fig. 7 gives the syntax-directed reasoning rules of DisLog (we hide "later" modalities for brevity). The rules `ALLOC, LENGTH, CALLPRIM, LETVAL, IFFALSE, IFFRUE, and STORE` are standard, apart from their mention of timestamps. In particular, the `ALLOC` rule does not generate a clock assertion. If desired, such an assertion can be obtained by applying the `MEMENTOPost` rule.

The `VALUE` rule asserts that if the symbolic evaluation of an expression ended at timestamp $t$, yielding a value $v$, then the postcondition $\Psi t v$ should hold. The `LOAD` rule extends the standard separation logic rule to prevent entanglement. Indeed, the $v \odot t$ assertion in the precondition witnesses that if $v$ is a location, then it must have been allocated before the current timestamp $t$. The `CASSUC` and `CASFAL` rules are similarly extended: they prevent entanglement by requiring that if the scrutinized value is a location, then it was allocated before the current timestamp.

The `CLOSEURE` and `Toplevel` rules produce an assertion $\text{Func } v f x e$ certifying that calling $v$ as a function will not cause entanglement. Obtaining this assertion for closures may be surprising at first, but is warranted by the following facts: (i) all the timestamps of locations captured by the closure are guaranteed to precede the closure’s allocation timestamp $t$ (by rule `MEMENTOPre`), and (ii) closures are immutable objects and, as such, cannot themselves create entanglement [Westrick et al. 2022]. Phrased differently, the locations of the environment are allocated before the closure itself, and thanks to immutability, this fact never changes. The `Func` predicate is persistent. The `CALL` rule allows calling a function, given the `Func` predicate. Proving that the environment was allocated before the current timestamp amounts to proving that the closure’s location itself was
allocated before the current timestamp, which is true since the closure’s location is already part of the expression (§4.4).

The \textbf{BIND} rule gives meaning to the notion of the “current timestamp” of an expression. Operationally, the evaluation of a term $K[e]$ at timestamp $t$ reduces the sub-expression $e$ until it reaches a value $v$ and an end timestamp $t'$. Then, the whole term $K[v]$ starts reducing at the new timestamp $t'$. The \textbf{BIND} rule paraphrases this operational behavior. The rule asserts that the user first has to reason about the sub-expression $e$ at the same current timestamp. The user has then to reason about the filled term $K[v]$ at a current timestamp $t'$, under the precondition that the sub-expression $e$ reduced to a value $v$ at end timestamp $t'$.

\textit{Reasoning About a Parallel Tuple.} A pivotal rule of DisLog is \textbf{Par}. Let’s first derive a naive version \textbf{ParWeak} of this rule below before focusing on the ultimate rule given in Fig. 7.

$$
\forall t_1, t_2. \quad t \leq t_1 \Rightarrow \wp(t, e_1 \parallel e_2) \{\Psi_1\} \quad t \leq t_2 \Rightarrow \wp(t, e_2) \{\Psi_2\} \quad \text{ParWeak}
$$

$$
\wp(t, e_1 \parallel e_2) \{\lambda t' \ell. \exists t_1', v_1, t_2', v_2. \Psi_1 \land t_1' \leq t' \land t_1' \neq t \land t_1' \neq t_2' \land t_2' \neq t \land t_1' \neq t_2' \land t_1' \neq t' \land t_2' \neq t' \land \{v_1; v_2\}\}
$$

This rule allows reasoning about a parallel tuple $e_1 \parallel e_2$ at current timestamp $t$. The premise universally quantifies over two fresh timestamps $t_1$ and $t_2$, which are used for $e_1$ and $e_2$, respectively. We focus on the left-hand side of the tuple as the right-hand side is handled similarly. The user should verify $e_1$ with the postcondition $\Psi_1$, under the hypothesis $t \leq t_1$ witnessing that $t$ precedes $t_1$. This information allows the user to safely acquire any location that was safe to acquire from $t$. Indeed, if the user has an assertion $\ell \odot t$, they can use the \textbf{ClockMono} rule to obtain an assertion $\ell \odot t_1$.

We emphasize that the above rule ensures that the two fresh timestamps $t_1$ and $t_2$ are unrelated. Hence, an assertion $\ell \odot t_1$ cannot be converted to an assertion $\ell \odot t_2$. This would indeed be unsafe, as a location allocated by the left task could be acquired by the right one, creating entanglement.

After the join point, the postcondition of the \textbf{ParWeak} rule asserts that $e_1$ reduced to a value $v_1$ at end timestamp $t_1''$, and that $e_2$ reduced to a value $v_2$ at end timestamp $t_2''$. The postcondition also produces witnesses that $t_1'$ and $t_2'$ precede the (new) current timestamp $t'$. Thanks to these two assertions any locations allocated by either of the two tasks are now accessible by any task at timestamp $t''$ such that $t' \leq t''$. Finally, the postcondition asserts that the parallel tuple itself reduced to a location $\ell$, pointing to the two resulting values $v_1$ and $v_2$.

Unfortunately, the \textbf{ParWeak} rule is tedious to use in practice. It fails to support a common pattern underlying our proof rules, which would allow the postconditions $\Psi_1$ and $\Psi_2$ of the newly forked tasks to depend on the tasks’ timestamps $t_1$ and $t_2$. This dependence is rendered impossible by the universal quantification of the timestamps $t_1$ and $t_2$. Our final rule \textbf{Par} presented in Fig. 7 facilitates the wished-for pattern. The premise of the \textbf{Par} rule quantifies universally over the two timestamps, and \textit{after} the quantification, allows the user to choose two existentially quantified postconditions $\Psi_1$ and $\Psi_2$ that can depend on the two timestamps. Moreover, the user is free to choose the postconditions after a potential ghost update; for example, to allocate an invariant that depends on both $t_1$ and $t_2$. The user should then verify the two parts of the parallel tuple with their respective timestamps, as in the \textbf{ParWeak} rule. Finally, the user has to show that the resulting values and timestamps entail the postcondition $\Psi$. This is formally expressed in the second line of the preconditions of the rule.

4.4 Soundness

Finally, we devote our attention to stating and proving soundness of DisLog. For our disentanglement logic to be sound it has to hold that the reduction of a program verified using the rules of DisLog leads to a disentangled program state. Our semantics is phrased in terms of a transition system that
The $S$ value is reducible. If the expression is a value, we can access the state interpretation, and deduce that the task state and the physical state. The definition of state interpretation predicate of a recipe [Jung et al. 2018, §6]. As usual, the WP is defined as a guarded fixpoint, and makes use of a weakest precondition modality that we refer to as wp. The generalization of the Iris WP makes use of the notion of weakest precondition modalities that we refer to as wp. The judgment $wpg \langle t, e \rangle \{\Psi\}$ asserts that a configuration facing a node of the task tree and a parallel tuple is reducible if at least one side of the pair is not a value (otherwise, a join should be possible), and each side that is not a value is reducible. The adequacy theorem of the Iris WP makes use of the notion of reducibility of a configuration that can make a scheduling step (either a head step, a fork, or a join) is reducible. The adequacy theorem asserts that the reducibility of a configuration facing an expression under an evaluation context amounts to the reducibility of this very expression. The theorem asserts that a configuration facing a node of the task tree and a parallel tuple is reducible if at least one side of the pair is not a value (otherwise, a join should be possible), and each side that is not a value is reducible.

An expression $e$ is safe if $(0,0,0)/t/e \xrightarrow{\text{step}} S'/T'/e'$ implies that either the configuration $S'/T'/e'$ is reducible, or that $e'$ is a value and $T'$ a single leaf. Our soundness theorem asserts that if an expression $e$ can be verified using DisLog, then it is safe.

**Theorem 4.1 (Soundness of DisLog).** If $wp \langle t, e \rangle \{\Psi\}$ holds, then $e$ is safe.

As the semantics of DisLang cannot progress when entanglement is detected, the soundness theorem asserts that $e$ cannot reach an entangled state. The formal proof Theorem 4.1 can be found in our Coq formalization [Moine et al. 2023b]. We detail below the main definitions and invariants.

**Definition of the Weakest Precondition.** The formal definition of the wp $\langle t, e \rangle \{\Psi\}$ assertion can be found in Fig. 9. The key to our approach is to define the wp modality with respect to a more general—hidden from the user—weakest precondition modality that we refer to as wp modality. The wp modality is parameterized not with a single timestamp, but a whole task tree: we found this generalization crucial for the various proofs to succeed. Nevertheless, reasoning always takes place at the leaves. Hence, we can hide the details of the task tree from the user.

The definition of the wp modality appears also in Fig. 9 and follows the traditional Iris recipe [Jung et al. 2018, §6]. As usual, the WP is defined as a guarded fixpoint, and makes use of a state interpretation predicate (or central invariant), written interp, which relates the ghost state and the physical state. The definition of wp cases on whether the expression is a value or not. If the expression is a value, we can access the state interpretation, and deduce that the task gets stuck if entanglement is encountered, ensured by the highlighted premises for head reductions in Fig. 4. Soundness of our logic thus must entail that verified programs cannot get stuck.

Since we use a small-step semantics in a parallel world, the definition of “not getting stuck” needs careful wording. In particular, it is not enough to say that “the configuration can take a step”. Indeed, one step of DisLang corresponds to a step of one task, whereas we want to ensure that every task can take a proper step. The adequacy theorem of the Iris WP makes use of the notion of reducibility to capture the fact that a thread can take a proper step. The judgment $red\langle T, e \rangle$ presented in Fig. 8 adapt this notion, ensuring that every task of the task tree can take a step. The RedSched rule asserts that a configuration that can make a scheduling step (either a head step, a fork, or a join) is reducible. The RedCtx rule asserts that the reducibility of a configuration facing an expression under an evaluation context amounts to the reducibility of this very expression. The RedPar rule asserts that a configuration facing a node of the task tree and a parallel tuple is reducible if at least one side of the pair is not a value (otherwise, a join should be possible), and each side that is not a value is reducible.

**Fig. 8. Reducibility of a configuration**

\[
\begin{align*}
\text{RedSched} & \quad \frac{S / T \parallel / e \xrightarrow{\text{sched}} S' / T' / e'}{red\langle T, e \rangle} \\
\text{RedCtx} & \quad \frac{red\langle T, e \rangle}{red\langle T, (K[e]) \rangle} \\
\text{RedPar} & \quad \frac{(e_1 \notin \mathcal{V} \lor e_2 \notin \mathcal{V})}{red\langle T_1 \otimes T_2, (e_1 || e_2) \rangle}
\end{align*}
\]

**Fig. 9. Definition of the weakest precondition modalities**
We first briefly explain the construction of ghost state in Iris abstractly, before detailing the part which can be thought as “step-indexed partial commutative monoids” [Jung et al. 2018], detailing a

\[ \alpha = \lambda e. \lambda g. (g \circ e) \]

\[ \text{RDeLeaf} \]
\[
\forall \ell. \ell \in \text{locs}(e) \implies \alpha(\ell) \leq_G t
\]
\[ \text{rootsde } \alpha G T e \]

\[ \text{RDePar} \]
\[
\text{rootsde } \alpha G (T_1 \otimes T_2) (e_1 || e_2)
\]
\[ \text{rootsde } \alpha G T e \]
\[ \forall t. t \in \text{locs}(K) \land t \in \text{leaves}(T) \implies \alpha(t) \leq_G t
\]

\[ \text{RDeCtx} \]
\[ \text{interp } (\sigma, \alpha, G) T e \]
\[ \text{edge } t t' \]
\[ \text{Func } v \ x \ e \]

Fig. 10. Definition of the state interpretation predicate and of base assertions

tree consists of a single leaf and the postcondition. Otherwise, if the expression is not a value, the wpg modality asserts that the configuration is reducible, and that for any possible step, the state interpretation must continue to hold, as well as the WP of the reduced program. Apart from its mention of timestamps, our WP distinguishes itself from the standard Iris WP by making the state interpretation available in the value case, and making use of our custom red judgment.

The State Interpretation Predicate. Our WP maintains a state interpretation predicate between each reduction step, which is defined in Fig. 10. We review its definition next.

We first focus on the roots disentanglement judgment \( \text{rootsde } \alpha G T e \). This judgment asserts each task of the expression \( e \) only uses locations allocated before its associated timestamp. This judgment allows stating the \text{MementoPre} rule. If the task tree consists of a single leaf \( t \), the \text{RDeLeaf} rule requires that the locations of \( e \) were allocated before \( t \). The \text{RDePar} rule requires that both sides of a parallel tuple satisfy the rootsde judgment. In the case of an evaluation context, \text{RDeCtx} requires that the judgment holds for the expression under the context, and that the locations occurring in the evaluation context itself are allocated before all the leaves of the task tree.

The state interpretation predicate also gives meaning to the ghost state from the physical state. We first briefly explain the construction of ghost state in Iris abstractly, before detailing the part of interp that concerns ghost state. In Iris, ghost state is defined in terms of so-called cameras (CMRA) which can be thought as “step-indexed partial commutative monoids” [Jung et al. 2018], detailing a resource algebra. Iris provides predefined notions of resource algebras. For example, the resource algebra \( \text{Auth}(M) \) describes the authoritative resource algebra over the resources \( M \). This resource algebra gives access to \( \bullet a \), the authoritative ownership of \( a \), and \( \circ b \), the fragmentary ownership of \( b \). Together, these two assertions entail that there exists an element \( c \) of the algebra such that \( a = b \cdot c \). The resource algebra \( \text{Set}(M) \) describes the set resource algebra, where the composition of resources is described by set union. For our state interpretation predicate, we define a ghost cell \( \gamma \) which we equip with the resource algebra \( \text{Auth}(\text{Set}(T \times T)) \). The ghost cell \( \gamma \) stores the computation graph and gives meaning to the precedence assertion.

Iris moreover provides a generic construction to define points-to assertions via the \text{gen_heap} library [Iris Development Team 2023]. This library defines a certain piece of ghost state, defines an assertion \( \text{Heap } \sigma \) that ties a store \( \sigma \) to this ghost state, and defines the points-to assertion \( \ell \mapsto_p \tilde{w} \) in terms of this ghost state. Moreover, the \text{gen_heap} library allows associating persistent information
to locations via a mechanism of meta assertions. In our case, we associate to each location $\ell$ the
timestamp $t$ of the task that allocated it, and write meta $\ell t$. The main property of this assertion is
that, from the knowledge meta $\ell t$ and meta $\ell t'$, we can deduce that $t = t'$.

We are now able to review the details of the definition of our state interpretation predicate
shown in the lower part of Fig. 10. First, it asserts that the domain of the store is the same as the
allocation map, and the roots disentanglement judgment. The state interpretation also asserts the
ghost authoritative ownership of the computation graph $G^\gamma$ and the ownership of the store via
the Heap $\sigma$ assertion. Moreover, the state interpretation asserts, for every mapping from a location $\ell$
to a timestamp $t$ in the allocation map $\alpha$, that the persistent knowledge meta $\ell t$ was set.

We define an edge between $t$ and $t'$ as a ghost fragmentary ownership of the singleton $\{ (t, t') \}$ $\gamma$. The conjunction of $G^\gamma$ and $\{ (t, t') \}$ $\gamma$ allows to deduce that $(t, t') \in G$. We define the prece-
dence assertion $t \prec t'$ as the reflexive-transitive-closure (rtc) over the edge predicate. The clock
assertion $\ell t$ is defined as a paraphrase of its informal definition. The location $\ell$ was allocated
before timestamp $t$ if there exists a timestamp $t_0$ such that $\ell$ was allocated at $t_0$, and $t_0$ precedes $t$.

The representation predicate of a $\lambda$-abstraction $\text{Func } v f \bar{x} e$ is a disjunction: either $v$ is a top-level
function, or a heap-allocated closure. In that case, we use a discarded fraction for the points-to
assertion, as the closure is immutable. The predicate also asserts the existence of a timestamp $t$
at which the closure was allocated, and that every location of its environment (the locations occurring
in $e$) was allocated before $t$. We make use of this knowledge to verify the Call rule of Fig. 7. The
closure’s location is allocated before the current timestamp (thanks to the rootsde judgment), but
since the locations of the environment were allocated before the allocation time of the closure itself,
they are also allocated before the current timestamp, and hence safe to acquire.

5 A HIGH-LEVEL LOGIC: DISLOG+

In this section, we introduce DisLog+, an almost standard concurrent separation logic allowing
proof of disentanglement for a large class of programs. DisLog+ is defined in terms of DisLog using
monotonicity arguments, a technique that first appeared in program logics targeting weak-memory
models [Dang et al. 2020; Kaiser et al. 2017; Mével et al. 2020].

5.1 Don’t Poke the Bear

Disentanglement is preserved by restricting reads: when a task acquires a location, the programmer
must ensure that this location was allocated by a preceding task. However, numerous programs
“don’t poke the bear”, that is, are disentangled because they do not comprise reads of shared, and
hence potentially hazardous, locations.

Determinacy-race-free programs are an example of such cautious programs. A determinacy
race [Feng and Leiserson 1999] occurs when two concurrent tasks access the same location atomi-
cally, and at least one of these accesses is a write. As noticed by Westrick et al. [2020], such race-free
programs are trivially disentangled: shared locations cannot be written to from different tasks,
which prevent the communication of freshly allocated data between tasks. Moreover, they noticed
that there exist some races that are also trivially disentangled. Races that fall into this category
are: (i) write-write races, because a write does not acquire a location, and (ii) read-write races on
data that was allocated before the beginning of the parallel phase, because tasks are allowed to
communicate previously-allocated data.

What is the common denominator of all these cautious programs? Rather than categorically
restricting reads, they demand a more nuanced consideration of writes. More precisely, these
programs ensure that when a task writes a value to a location, this value is safe to read for any
task that can access the said location. Race-free programs prevent concurrent reads, because a task
must have unique ownership of a location to write to it. Write-write races do not restrict writes, as there is no concurrent read, and read-writes races are permitted as long as the written value was allocated before the beginning of the parallel phase.

For this large class of programs that don’t poke the bear, we provide an almost traditional separation logic called DisLog+. By “traditional”, we mean that the weakest precondition of DisLog+ takes a form which does not mention timestamps (§5.2). Moreover, its syntax-directed reasoning rules do not mention clock nor precedence assertions: they are the standard reasoning rules of concurrent separation logic (§5.3). By “almost”, we stress that DisLog+ restricts the use of ghost state to prevent races, but is otherwise a standard separation logic. DisLog+ is hence ideally suited to reason about race-free programs. To cater to the benign races identified above, we extend DisLog+ with (i) write-only assertions to reason about write-write races (§5.4) and (ii) three rules to reason about read-write races on previously allocated data that we refer to as the objectivity lemmas (§5.5).

### 5.2 Monotonicity to the Rescue

Our development of DisLog+ was triggered by two observations about race-free programs: (i) race-free programs ensure that, when a task accesses a location, any value referenced by the location is safe for the task to acquire, and that (ii) this property is monotonic with respect to the precedence pre-order. Indeed, if all the pointed-to values are safe to read for a given task, then these values are also safe to read for any of the task’s descendants in the computation graph.

We define a new separation logic, in which every assertion is parameterized by a timestamp, called the ambient timestamp, and is monotonic with respect to the precedence pre-order. Fig. 11 presents the formal definitions of these assertions, written $P$ and of type $\forallProp$.

The user can always project a $\forallProp$ assertion $P$ to a particular timestamp $t$ in $iProp$ via the construction $P@t$. Conversely, the lifting construction $[\Phi] \triangleq \lambda_\Phi$ allows to lift an $iProp$ assertion $\Phi$ into $\forallProp$. Hence, the whole ghost-state theory of $iProp$ is available in $\forallProp$. When the context allows it, we write $\Phi$ instead of $[\Phi]$ for the lifting of an $iProp$ assertion into $\forallProp$. The entailment of $\forallProp$ (written $\Rightarrow_{\forallProp}$) is defined using the entailment of $iProp$ (written $\Rightarrow_{iProp}$). The definition ensures that an entailment $P \Rightarrow_{\forallProp} P'$ is valid if and only if, for any timestamp $t$ the projection $P@t$ of the premise entails the projection $P'@t$ of the conclusion.

Fig. 11 also defines the assertions relative to DisLog+. The $\ell \odot now$ assertion asserts that $\ell$ was allocated before the ambient timestamp. This is a persistent assertion, whose monotonicity is ensured by the ClockMono rule. Again, we overload this assertion to arbitrary values and collection of values. The key idea of DisLog+ is its definition of the points-to assertion. The assertion $\ell \mapsto_p w$ is defined as the conjunction of the points-to assertion in $iProp$, written $[\ell \mapsto_p v]$, as well as the knowledge that every value pointed-to by the location was allocated before the ambient timestamp, using the $\widehat{w} \odot now$ assertion. Hence, the points-to assertion of $\forallProp$ asserts that every load for this location is safe for this particular task, and any subsequent task!

The WP of DisLog+ takes the form $\wpm e \{\lambda v. P\}$, where the variable $v$ denotes the resulting value of $e$ and is bound in $P$. To abstract over the details of the postcondition, we write $Q$ instead...
We showcase the most important reasoning rules of DisLog+ in Fig. 12, which are similar to the reasoning rules of the original concurrent separation logic with fractional permissions [Bornat et al. 2005]. These rules are expressed at the \( v\text{Prop} \) level, where the horizontal bar stands for \( v\text{Prop} \) entailment. In particular, the points-to assertion occurring in the rules is the one defined in Fig. 11, guaranteeing that any load will be safe. Nevertheless, all the rules of Fig. 12 are derived from the rules of DisLog (§4.3) using the Conversion rule.

The user can freely go between DisLog+ and DisLog using the following Conversion rule.

\[
(P \vdash_{\text{Prop}} \text{wpm } e \{Q\}) \iff (\forall t. P @ t \vdash_{\text{Prop}} \text{wp } (t, e) \{\lambda t'. \text{e} (Q \text{e} @ t')\}) \quad \text{(Conversion)}
\]

This rule needs a careful reading. It asserts that the precondition \( P \) entails \( \text{wpm } e \{Q\} \) in \( v\text{Prop} \) if and only if (in the meta-logic), for any timestamp, the projection of the precondition at this timestamp entails the WP of DisLog with the postcondition projected at the end timestamp. Notice that the Conversion rule is an equivalence. While it is not surprising that a specification in DisLog+ is valid in DisLog (the former being more restrictive than the latter), the converse is also true: the user can use the full power of DisLog rules to verify a DisLog+ interface.

The soundness of DisLog+ is a direct corollary of the soundness of DisLog (Theorem 4.1), thanks to the Conversion rule.

**Theorem 5.1 (Soundness of DisLog+).** If \( \text{wpm } e \{\lambda . \text{e} \} \) holds, then \( e \) is safe.

### 5.3 Reasoning Rules of DisLog+

We showcase the most important reasoning rules of DisLog+ in Fig. 12, which are similar to the reasoning rules of the original concurrent separation logic with fractional permissions [Bornat et al. 2005]. These rules are expressed at the \( v\text{Prop} \) level, where the horizontal bar stands for \( v\text{Prop} \) entailment. In particular, the points-to assertion occurring in the rules is the one defined in Fig. 11, guaranteeing that any load will be safe. Nevertheless, all the rules of Fig. 12 are derived from the rules of DisLog (§4.3) using the Conversion rule.

The rules we present in Fig. 12 prevent races. Indeed, the only way to allow a race is by sharing a points-to assertion between tasks, which is only possible via invariants [Jung et al. 2018, §2.2]. Because invariants can only be installed for assertions of type \( i\text{Prop} \), but points-to assertions in DisLog+ are of type \( v\text{Prop} \), DisLog+ rules out races by construction. We alluded to this restricted use of Iris ghost state by referring to DisLog+ as an “almost” standard separation logic (§5.1).

The \( \text{ALLOC}+ \) rule produces a valid points-to assertion, that is, both the ownership information and the proof that the default value is safe to read at the ambient timestamp. As the default value \( v \) occurs in the expression \( \text{alloc } i \text{v} \), if \( v \) is a location, then it was already acquired, and hence already safe. This is reminiscent of the MementoPre rule (Fig. 6). The \( \text{STORE}+ \) rule is also standard and preserves the fact that any subsequent load will be safe. The stored value \( v \) occurs in the expression \( t[i] \leftarrow v \), and is hence safe to read. The \( \text{LOAD}+ \) rule is the standard rule of separation logic, as it internally rests on the fact that all the values pointed-to by the location are safe to read. Finally, the \( \text{PAR}+ \) rule heavily makes use of the monotonicity of \( v\text{Prop} \) assertions. Indeed, the two postconditions \( Q_1 \) and \( Q_2 \) are valid for the end timestamp of the two forked tasks. Hence, they are also valid for the end timestamp of the parallel tuple, that succeeds them.
which in DisLang are represented by arrays of size 1

while preserving the invariant. In DisLog+, invariants are restricted to $iProp$

A write-write race occurs when two or more tasks race to write to a shared location, but neither of
them (or any other task) ever reads from the said location. Write-write races are always disentangled,
as a write does not acquire any location. However, from the point of view of functional correctness,
write-write races are subtle: once the tasks join and the program reads the shared location, all the
outcomes of the race should be taken into account.

To verify such races in more standard Iris settings, the user typically installs an invariant
containing the points-to assertion, quantifies existentially over the pointed-to value, and constrains
it using ghost state. This existential quantification allows the user to change the pointed-to value
while preserving the invariant. In DisLog+, invariants are restricted to $iProp$ assertions, and thus
the user cannot store a $(aProp)$ points-to assertion inside an invariant. To allow the verification
of write-write races in DisLog+ without the need of an invariant, we introduce the notion of a
fractional write-only assertion presented in Fig. 13.

A write-only assertion takes the form $\ell \Rightarrow p X$, where $p$ is a list of ghost names, $p$ a positive
fraction less or equal to 1, and $X$ a set of possible values. When $p = 1$, the set $X$ contains all the
values possibly written to $\ell$. The write-only assertion comes with a companion assertion $\text{orig} p v$, which is persistent and describes the original value of the points-to assertion. The $\text{WOSTart}$ rule
consumes a points-to assertion and produces an orig assertion and an empty write-only assertion.
The $\text{WOFrac}$ rule asserts that the write-only assertion is fractional: the user can always arbitrarily
split and join it. The $\text{WOSTore}$ rule allows executing a store operation, overwriting the set of
possible values. This rule only requires a fraction of the write-only assertion: a concurrent task
could have another fraction and race to write.

Fig. 13 also includes two rules for getting back a points-to assertion from a write-only assertion.
In both cases, the full fraction 1 must be given back. The $\text{WOCancel}$ rule can be used if no write
occurred, as witnessed by the empty write-only assertion. The rule produces the original points-to
assertion. If at least one write has occurred, the $\text{WOEnd}$ rule can be used. The rule produces a
points-to assertion and a proof that the pointed-to value is in the set of possible values.

The definition of write-only assertions appears in our Coq formalization [Moine et al. 2023b].
This definition makes use of standard ghost state and in particular a cancellable invariant [Jung et al.
2018, §7.1] in which a points-to assertion of DisLog is stored. Notably, the assertion $\ell \Rightarrow p X$
carries not only information on the contents of the cancellable invariant, but also a witness $X \cap now$ that
the set of possible values was allocated before the ambient timestamp. Hence, after an application
of the $\text{WOEnd}$ rule, we can reconstruct back a $aProp$ points-to by canceling the invariant and
exhibiting a witness that the pointed-to value was allocated before the ambient timestamp.

While write-only assertions fit well in the context of $aProp$, we stress that they are not specific to
it. Similar definitions can be proposed for regular points-to assertions at the $iProp$ level, dropping
assertions related to timestamps. In our discussion of write-only assertions, we focus on references,
which in DisLang are represented by arrays of size 1. To target arbitrary arrays, we assume that
our approach can be generalized to a more detailed interface with a per-index write-only points-to
assertion. This generalization should be purely mechanical.
5.5 Many Read-Write Races are Disentangled: Objectivity Lemmas

Read-write races can create entanglement: a task could communicate a memory location it allocated to a concurrent task. Verifying that such races are safe often requires the full expressiveness of DisLog. However, some read-write races are trivially disentangled: if written values are unboxed (that is, not allocated in the heap), or were allocated before the beginning of the race. This section explains how to reason about such races within DisLog+.

In the extreme case where a location points to a block of unboxed values, read-write races are tolerated without additional work. Recall (Fig. 11) that \( t \mapsto p \hat{w} \triangleq [t \mapsto p \hat{w}] \ast \hat{w} \odot \text{now} \). If \( \hat{w} \) contains only unboxed values, the assertion \( \hat{w} \odot \text{now} \) holds trivially true, and we thus have that \( t \mapsto p. \hat{w} \triangleq [t \mapsto p. \hat{w}] \). Therefore, the points-to assertion of \( t \) can be stored directly inside an invariant, and read-write races on \( t \) can be verified, as long writes concern unboxed values.

In a more general case, Fig. 14 presents an interface of “objectivity lemmas” to reason about trivially disentangled read-write races. Objectivity lemmas offer two mechanisms. First, they allow witnessing that a set of locations were allocated before a program point (rules GetClock and MementoPre+). Second, they allow sharing a points-to assertion through an invariant, and allow updating this points-to assertion as long as new values are unboxed or were allocated before the beginning of the race (rules SplitSubjObj and Objectivize).

To witness that a set of locations were allocated before a given program point, the user can use two rules and combine their result using the equivalence \( (A_1 \cup A_2) \odot \text{now} \vdash A_1 \odot \text{now} \ast A_2 \odot \text{now} \). First, the GetClock rule allows extracting from a points-to assertion that every pointed-by value was allocated before the ambient timestamp. Second, the MementoPre+ rule asserts that every location occurring in the current expression was allocated before the ambient timestamp.

The SplitSubjObj rule allows in particular sharing a points-to assertion through an invariant, while fixing the set of possibilities for newly written values. We present the general form of the rule, adapted from Cosmo [Mével et al. 2020, §4.1]. The SplitSubjObj rule asserts that owning a vProp assertion \( P \) is equivalent to owning its iProp projection to some timestamp \( [P@t] \) (the objective part of \( P \)), and the information that this timestamp precedes the ambient timestamp, written \( \uparrow t \) (the subjective part of \( P \)). The assertion \( \uparrow t \) is persistent and defined as \( \lambda t'. t \ll t' \). The objective part \( P@t \) is an iProp assertion and can hence be shared through an invariant. The subjective part \( \uparrow t \) cannot be shared through an invariant, but it can be given to subsequent tasks and used to convert back the objective part into the original vProp assertion, by using again the SplitSubjObj rule.

We now focus on a contrived example to illustrate how the objectivity lemmas are intended to be used, and why an additional rule, Objectivize, is needed. Sec. 6.1 and 6.3 provide more realistic examples, based on the same idea. Our contrived example is:

\[
\text{let } t = \text{alloc } 1 () \text{ in } (t[0] || t[0] \leftarrow t)
\]

This example allocates a reference \( t \) (that is, an array of size 1), initialized to ( ). It then forks two tasks, one reading from \( t \) and the other storing \( t \) inside itself. This is a trivially disentangled read-write race: the only written value is allocated before the beginning of the race.
To verify this example, we first use the \texttt{Alloc} rule (Fig. 12) and obtain the assertion $\ell \mapsto [()]$. Then, we use the \texttt{MementoPre} rule to generate a witness $\ell \ominus \text{now}$ that $\ell$ was allocated before the execution of the par. Then, we use the \texttt{SplitSubjObj} rule on the assertion $(\ell \mapsto [()] \ast \ell \ominus \text{now})@t$. We obtain the assertion $\uparrow t \ast ((\ell \mapsto [(]) \ast \ell \ominus \text{now})@t)$. Unfolding definitions, the objective part is equivalent to $(\ell \mapsto [(])@t \ast \ell \ominus t$. We then allocate an invariant containing the assertion:

$$\exists v. (\ell \mapsto [v])@t \ast \neg v = () \lor v = \ell$$

Next, we apply the \texttt{Par} rule (Fig. 12), and give each task a copy of the invariant, of the assertion $\uparrow t$ and of the assertion $\ell \ominus t$. For the two tasks, the proof is similar. First, we open the invariant. Then, use the \texttt{SplitSubjObj} rule to convert back the assertion $(\ell \mapsto [v])@t$ into $\ell \mapsto [v]$, instantiating the existential with $t$. We then execute the load or the store.

Finally, comes the time to close the invariant. We cannot use the \texttt{SplitSubjObj} rule again because the existential quantification of this rule would generate a fresh timestamp $t'$, distinct from $t$. Thankfully, the \texttt{Objectivize} rule comes to save the day. This rule allows us to generate an assertion $\lceil (\ell \mapsto \hat{w})@t \rceil$ as long as we can provide the assertion $[\text{locs}(\hat{w}) \ominus t]$, where $\text{locs}(\hat{w})$ denotes the set of locations of the list of values $\hat{w}$. We apply the \texttt{Objectivize} rule, instantiating $\hat{w}$ by $[v]$, do a case analysis on $v$ and end the proof, given that we have at hand the assertion $\ell \ominus t$. Notice that, instead of writing $\ell$ into itself, we could have written any unboxed value, or any location that was allocated before $\ell$ itself.

6 EVALUATION

We showcase DisLog+ and DisLog via a range of case studies. We first focus on the scratch example of Sec. 2, and prove it correct in DisLog+ (§6.1). Then, we illustrate how to reason about a write-write race using write-only assertions (§6.2) based on a parallel lookup in a lazy collection. We conclude with a case study on concurrent hashing and deduplication (§6.3 and §6.3).

Deduplication refers to the process of removing duplicates from a collection. This task can be efficiently done in parallel using concurrent hashing: each task tries to insert elements into a shared concurrent hash set, which by construction does not store duplicates. If the collection is fully allocated beforehand, we use a folklore hash set [VerifyThis 2022], and verify both the hash set interface and the duplication itself entirely within DisLog+ (§6.3), thanks to the objectivity lemmas. In the case of a lazy collection, where elements may not be already allocated prior to the parallel phase, the previous approach cannot be directly used: naively applying the previous deduplication algorithm would result in entanglement, and so a different deduplication algorithm is needed. We address this issue by first partially removing duplicates in parallel with a more subtle hash set, then getting rid of the remaining duplicates by calling the previous deduplication function. Interestingly, the proof requires the full power of DisLog (§6.4).

In the case studies, we write a non-recursive function as $\lambda x.e$, which is a sugar for $\mu_\_\lambda x.e$. where _ denotes an anonymous binding. We add a hat and write $\hat{\lambda}$ to distinguish top-level functions. We write $e_1 ; e_2$ for a sequence, which is encoded as let $\_ = e_1$ in $e_2$.

6.1 The scratch Example

We first give an interface to a spin-lock. The verified code is a direct translation of the spin-lock presented earlier (§2.2), which is implemented as a pair of closures sharing a reference to a boolean named $r$, initialized to false. The first closure attempts a lock by doing a CAS on $r$ from false to true. The second closure releases the lock by setting the reference $r$ to false.

Our specification of locks in DisLog+ appears in Fig. 15 and is very similar to the standard specification of locks in high-order separation logic [Gotsman et al. 2007; Svendsen and Birkedal 2014]. In DisLog+, a lock must be restricted to protect an $iProp$ assertion $\Phi$, as a lock protects
an invariant. The precondition of the specification of new_lock consumes $\Phi$. The postcondition produces a location $\ell$ pointing to a pair of closures $(l, u)$, for locking and unlocking, respectively, as well as an iProp assertion $l\ u\ \Phi$, which is persistent and asserts that the $l$ and $u$ describe a valid lock. The specification of a call to the closure $l$ requires a valid lock, and returns a boolean. If this boolean is true, then the lock was successfully locked: the user gains the protected assertion $\Phi$ as well an exclusive token locked $l$, witnessing that the lock is now locked. This token is required to call the closure $u$, as well as $\Phi$, which has to be given back when the user wants to unlock the lock.

We conduct the proofs of the interface of Fig. 15 entirely within DisLog+. Indeed, we are in an extreme case: the shared reference points-to a boolean, which is unboxed. Hence, the points-to of DisLog+ is equivalent to the points-to of DisLog ($\S$5.5). Thus, we are able to define the lock $l\ u\ \Phi$ assertion using an invariant that stores directly the points-to assertion of the shared reference.

We make use of the interface of locks we just presented, as well as the objectivity lemmas, and verify the following interface for the scratch example.

\[
\begin{align*}
\forall \ell. \; \ell \mapsto \text{defaultElem}^N \; \rightarrow \; \text{wpm}(\text{doWork}[\ell]) \{ \lambda \ldots. \; Q_i \; \rightarrow \; \exists \mathbf{w}. \; \ell \mapsto \mathbf{w} \} \\
\text{wpm}(\text{scratch}[]) \{ \lambda \ldots. \; Q_0 \; \rightarrow \; Q_1 \}
\end{align*}
\]

Recall that the scratch example allocates a shared reference, which is protected by a lock while two parallel tasks attempt to access it. After allocating the shared reference, we have a points-to assertion of the form $\text{shared} \mapsto \text{defaultElem}^N$. We use the GetClock rule to extract an assertion $\text{defaultElem} \ominus \text{now}$. Then, we use the SplitSubjObj rule and obtain the assertion $\uparrow t$ as well as the assertion that will be protected by the lock $(\text{shared} \mapsto \text{defaultElem}^N)@t$. Each task gets an assertion $\uparrow t \ast \text{defaultElem} \ominus t$. Then, if a task wins the lock, we reconstruct a points-to assertion with the SplitSubjObj rule, call the doWork function, call the cleanScratchPad function, and restore the invariant protected by the lock using the Objectivize rule.

### 6.2 Parallel Lookup in a Lazy Collection

The left part of Fig. 16 presents the code of a parallel loop parfor $[a; b; h]$, calling the function $h$ for each index between $a$ and $b$. The presented code is a direct translation of the implementation used in the standard library of MPL [MPL Development Team 2022]. The specification of parfor appears below and should be unsurprising. The precondition requires, for every index $i$ between $a$ and $b$, that $h[i]$ is safe and satisfies a postcondition $Q_i$. The postcondition of parfor $[a; b; h]$ produces the iterated conjunction of the postconditions.

The right part of Fig. 16 presents the code of the lookup $[k; n]$ function that searches for a non-unit value in the lazy collection $k$ up to index $n$. To do so, the function uses a reference $r$, and a closure $h$ that takes an index $i$, produces the $i$-th index of the lazy collection, and writes it in $r$ if it is non-unit. The closure $h$ is then called in parallel for every index between 0 and $n$. This is a typical example of a write-write race: each call on $h$ may write in $r$, but never read from it.

The specification of lookup $[k; n]$ appears at the bottom of Fig. 16. Its precondition requires that $k$ is valid lazy collection: between indices 0 and $n$, $k$ produces a value satisfying a predicate $K$. The postcondition of the specification produces a value $v$ and asserts the existence of $\mathbf{w}$, the collection...
where

whether a non-unit value is in the lazy collection $k$.

interface hence restricts insertions to a set of values that were allocated before the hash set itself.

indeed, the $\text{put}$ auxiliary function does a CAS, or an auxiliary closure, which tries to insert $x$ at a given index, originally the hash of $x$, using a CAS. If this index is already taken by a collision, the $\text{put}$ closure tries the next index. (We do not resize: the $\text{put}$ function loops if the table is full.) The function $\text{elems} [s; d; x]$ function returns the elements of $s$: that is, all the elements distinct from the dummy element $d$. Occurrences of $d$ are removed via a call to a dedicated $\text{filter}_{\text{compact}}$ function, which filters the array, and returns a compacted array where $d$ does not appear anymore. For brevity here, we omit the implementation of $\text{filter}_{\text{compact}}$, as it can be implemented entirely race-free and therefore disentangled. We instead focus on the nuance of disentanglement for concurrent operations on the hash set.

The hash set can be used to insert values concurrently and in parallel. However, in order to preserve disentanglement, the user should only insert values that were allocated before the beginning of the parallel phase [Westrick 2022]. Indeed, the $\text{put}$ auxiliary function does a CAS operation on an $a\text{ priori}$ arbitrary index, which may have been filled by a concurrent task. Our interface hence restricts insertions to a set of values that were allocated before the hash set itself.

\[ \text{parfor} \triangleq \mu f.\lambda [a; b; h]. \]
\[ \text{lookup} \triangleq \lambda [k; n]. \]
\[ \text{let } r = \text{alloc } 1 \text{ in} \]
\[ \text{let } h = \lambda [i], \text{let } x = k [i] \text{ in} \]
\[ \text{if } x == () \text{ then } () \text{ else } r[0] \leftarrow x \text{ in} \]
\[ \text{parfor } [0; n; h] : r[0] \]

Fig. 16. Case study: parallel lookup in a lazy collection itself. The found $n \bar{w} v$ judgment asserts that $\bar{w}$ has size $n$ and that either $v$ is not the unit value and occurs in $\bar{w}$, or $\bar{w}$ is the unit value and every value in $\bar{w}$ is the unit value. It is defined as:

\[ \text{found } n \bar{w} v \triangleq |\bar{w}| = n \land (v \neq ()) \land v \in \bar{w} \lor (v = ()) \land \forall w. w \in \bar{w} \implies w = () \]

The proof of our specification makes use of a write-only assertion (§5.4). Indeed, just after the allocation of $r$, we convert its points-to-assertion into a write-only assertion $r \models^\delta_1 \emptyset$, and split it into $n$ fractions. Then, we call the parfor specification and instantiates $Q$ with:

\[ \lambda_. \exists v. K v \models^\delta_1 n \models^\delta_1 \{ v \} \lor (v = ()) \land \forall w. w \in \bar{w} \implies w = () \]

This postcondition asserts that the lazy collection produced a value and that if it is not the unit value, then it was written into $r$, else nothing was written to $r$. After applying the specification of parfor, we gather all the fractions of the write-only assertion. We then do a case analysis on whether a non-unit value is in the lazy collection $k$, and convert the write-only assertion back to a normal points-to-assertion accordingly.

6.3 Deduplication via Concurrent Hashing

In the next two sections, we suppose a user-chosen capacity $C$, which bounds the number of elements within hash sets. We also suppose a hash function from values to integers.

We present a folklore [VerifyThis 2022] concurrent, lock-free, fixed-capacity hash set using open addressing and linear probing to handle collision [Knuth 1998]. The code of our hash set appears in the upper part of Fig. 17. The hash set consists of an array of size $C$. When created, the array is filled with a dummy element $d$, which cannot be inserted in the hash set as it denotes an empty slot. Inserting an element is done by the $\text{add} [s; d; x]$ function, where $s$ is the hash set, $d$ the dummy element and $x$ the element being inserted. The function calls the $\text{put}$ auxiliary closure, which tries to insert $x$ at a given index, originally the hash of $x$, using a CAS. If this index is already taken by a distinct value, potentially due to a collision, the $\text{put}$ closure tries the next index. (We do not resize: the $\text{put}$ function loops if the table is full.) The function $\text{elems} [s; d]$ function returns the elements of $s$: that is, all the elements distinct from the dummy element $d$. Occurrences of $d$ are removed via a call to a dedicated $\text{filter}_{\text{compact}}$ function, which filters the array, and returns a compacted array where $d$ does not appear anymore. For brevity here, we omit the implementation of $\text{filter}_{\text{compact}}$, as it can be implemented entirely race-free and therefore disentangled. We instead focus on the nuance of disentanglement for concurrent operations on the hash set.

The hash set can be used to insert values concurrently and in parallel. However, in order to preserve disentanglement, the user should only insert values that were allocated before the beginning of the parallel phase [Westrick 2022]. Indeed, the $\text{put}$ auxiliary function does a CAS operation on an $a\text{ priori}$ arbitrary index, which may have been filled by a concurrent task. Our interface hence restricts insertions to a set of values that were allocated before the hash set itself.
The representation predicate of a hash set \( A \) is the preservation of the elements \( \text{elems} \) and their deduplication \( \text{dedup} \). The proof is straightforward: each task gets an assertion \( hset \) that is not in the array. The postcondition returns a fresh \( \text{hset} \) with no duplicates and has the same elements as \( \text{elems} \).

\[
\begin{align*}
\text{init} & \triangleq \hat{\lambda}[d]. \text{alloc } C \ d & \text{elems} & \triangleq \hat{\lambda}[s; d]. \text{filter} \text{compact} \ [s; d] \\
\text{add} & \triangleq \hat{\lambda}[s; d; x]. & \text{dedup} & \triangleq \hat{\lambda}[d; t]. \\
\text{let put} & = \mu f. \lambda[i]. \\
& \text{if } (\text{CAS } \ell i d x \lor \ell[i] == x) \text{ then } () \\
& \text{else } f \ [(i + 1) \mod C] \text{ in} \\
\text{put} & [\text{hash} \ x] \mod C \\
\text{wpm} (\text{init} \ [d]) \{ \lambda s. \text{hset} \ s \ A \ \emptyset 1 \} & \text{wpm} (\text{elems} \ [s; d]) \{ \lambda t. \exists \tilde{w}. \ t \mapsto \tilde{w} * \overset{r}{\text{deduped}} \tilde{w} \ X \} \\
\overset{\text{\( \{\{d \notin A\} \cup \{\text{now}\}\}\} \text{wpm} (\text{add} \ [s; d; x]) \{ \lambda \_ \text{hset} \ s \ A \ (X \cup \{x\}) \ p \} \\
\overset{\text{\( \{\{d \notin \bar{d}\} \} \text{wpm} (\text{dedup} \ [d; t]) \{ \lambda t'. \exists \tilde{w}. \ t' \mapsto \tilde{w} * t \mapsto p \bar{d} * \overset{r}{\text{deduped}} \tilde{w} \bar{d} \} \\
\overset{\text{\( \bar{d} \notin \bar{d} \\}} \text{wpm} (\text{dedup} \ [d; t]) \{ \lambda t'. \exists \tilde{w}. \ t' \mapsto \tilde{w} * t \mapsto p \bar{d} * \overset{r}{\text{deduped}} \tilde{w} \bar{d} \} \\
\text{Fig. 17. Case study: deduplication of an array by concurrent hashing}
\end{align*}
\]

\( [\text{hset} \ s \ A \ X \ p] \)

The representation predicate of a hash set \( s \) is written \( \text{hset} \ s \ A \ X \ p \), where \( d \) is the dummy element, \( A \) a set of values that were witnessed as allocated before the hash set, \( X \) a set of values that were inserted, and \( p \) a fraction in (0; 1). This predicate can be split and joined, allowing for parallel use.

\[
\text{hset} \ s \ d \ A \ (X_1 \cup X_2) \ (p_1 + p_2) \iff \text{hset} \ s \ d \ A \ X_1 \ p_1 \iff \text{hset} \ s \ d \ A \ X_2 \ p_2
\]

Such a predicate is created by the \( \text{init} \ [d] \) function. Its precondition requires a witness that a set \( A \) of values were allocated before the current timestamp, via the \( \text{A} \cup \text{now} \) assertion. Such an assertion can be obtained via the \text{GetClock} and \text{SplitSubjObj} rules. The precondition also requires that the dummy element \( d \) is not an element of \( A \). The postcondition produces a valid empty hash set with fraction 1. The specification of \( \text{add} \ [s; d; x] \) requires a valid hash set with an arbitrary fraction, and that the element being inserted is in the authorized set of values. The specification of \( \text{elems} \ [s; d] \) consumes a hash set with fraction 1 with content \( X \) and produces an array \( \ell \) with content \( \tilde{w} \). The deduped \( \tilde{w} \ X \) assertion asserts that \( \tilde{w} \) contains no duplicate and has the same elements as \( X \):

\[
\text{deduped} \tilde{w} \ X \triangleq \text{NoDup} \tilde{w} \wedge (\forall v. v \in \tilde{w} \iff v \in X)
\]

The proofs of the hash set interface of Fig. 17 rest on the objectivity lemmas. Indeed, parallel insertion may imply read-write races, but only on data allocated before the parallel phase. Intuitively, the hset predicate involves a cancellable invariant, storing an assertion \( (s \mapsto \tilde{w})@t \), as well as an assertion \( A \cup t \), where \( t \) comes from an application of the \text{SplitSubjObj} rule. The invariant also records that \( \text{locs}(\tilde{w}) \subseteq A \), allowing the use of the \text{Objectivize} rule during the proofs. In addition to this cancellable invariant, the hset predicate also involves the (persistent) assertion \( \uparrow t \), allowing to retrieve and update the points-to assertion of \( s \) using the \text{SplitSubjObj} rule.

Fig. 17 also presents the code and specification of the dedup \([d; t]\) function. This function deduplicates the array \( \ell \) using our concurrent hash set. The function first creates a hash set \( s \). Then, the function allocates a closure which, given an index \( i \), inserts the element \( \ell[i] \) inside \( s \). Next, the function calls the closure in parallel for every index of the array. Finally, the function returns the elements of the hash set. The precondition requires that \( \ell \) points to an array \( \bar{d} \) and the existence of a dummy element \( d \) that is not in the array. The postcondition returns a fresh location \( \ell' \) pointing to an array \( \tilde{w} \) that is a deduplicated version of \( \bar{d} \). Making use of our hash set, the proof is straightforward: each task gets an assertion \( \text{hset} \ s \ d \bar{d} \emptyset \ (1/|\bar{d}|) \), enabling them to
We cannot reuse the hash set of the previous section to deduplicate a lazy collection in parallel: its design has two consequences. First, duplicates may occur in the hash set: two tasks could insert the same element at distinct indexes. The number of tasks bounds the number of duplicates. Second, this technique [Herlihy and Shavit 2012]. The first array is similar to the hash set of the previous section and contains the inserted elements. The second array stores task identifiers, represented as (unboxed) integers. Each task is given a distinct identifier. Intuitively, before loading or writing an index of inserting an element at index \( i \), a task must ensure with a CAS that its identifier is written inside the second array at the same index. Otherwise, the task is not allowed to load or write the desired index in the first array. The races on the second array are disentangled: it stores only unboxed integers. This design has two consequences. First, duplicates may occur in the hash set: two tasks could insert the same element at distinct indexes. The number of tasks bounds the number of duplicates. Second, disentanglement of loads on the first array relies on a subtle invariant: if a task has written its identifier at an index of the first array, the same element at distinct indexes. The number of tasks bounds the number of duplicates. Second, disentanglement of loads on the first array relies on a subtle invariant: if a task has written its identifier at an index of the second array, this task uniquely owns the same index of the first array. The races on the second array are disentangled: it stores only unboxed integers. This design has two consequences. First, duplicates may occur in the hash set: two tasks could insert the same element at distinct indexes. The number of tasks bounds the number of duplicates. Second, disentanglement of loads on the first array relies on a subtle invariant: if a task has written its identifier at an index of the second array, this task uniquely owns the same index of the first array.

Fig. 18 presents the implementation of our new hash set. The \( \text{init} \) function initializes the first array with the dummy element \( d \) and the second array with a dummy identifier \(-1\). The \( \text{add} \) function inserts the element \( x \) inside the hash set \( s \) with dummy element \( d \) and the task identifier \( u \). This function differs from the add function of the previous section in two points. First, it is parameterized by the identifier of the task inserting the element. Second, instead of inserting an element at index \( i \) using a direct CAS, it uses the auxiliary function \( \text{tryput} \).

The \( \text{tryput} \) function first loads the first array \( l_1 \) and the second array \( l_2 \) of the hash set. Then, the function tests if it has already written its identifier at index \( i \) inside \( l_2 \). If yes, or if a CAS succeeds in writing the identifier \( u \), the task has unique ownership of the index \( i \) in \( l_1 \). The task can then load the content of \( l_1[i] \), and tries to insert the desired element.
To prove this data structure correct, the full power of DisLog is needed. The lower part of Fig. 18 shows the specifications of init and add, where \( n \) is the number of tasks that will use the hash set. They involve a representation predicate \( lhset \ s \ d \ u \ X \ t \), which asserts that the hash set \( s \) with dummy element \( d \) can be used with the task identifier \( u \), contains elements in \( X \) and is valid at timestamp \( t \). The specification of init generates \( n \) pieces of the \( lhset \) predicate, one for each task. The add function must be called with the correct identifier. The key idea is that the \( lhset \) representation predicate is monotonic with respect to the precedence pre-order. We derive similar specifications in DisLog+ using the \texttt{CONVERSION} rule, confining the timestamp-related reasoning.

Given a number of tasks \( P \), our deduplication function \( \text{dedup}_{\text{lazy}} \ [d; k; n] \) allocates a hash set and generates \( P \) parallel tasks using \texttt{parfor}. For each element of its designated range, each task sequentially generates the element on-the-fly before trying to insert it inside the lazy collection. When all tasks end, the \( \text{dedup}_{\text{lazy}} \) function extracts the elements of the hash set, and remove the remaining duplicates using the previous dedup function.

The last part of Fig. 18 presents the specification of our deduplication function \( \text{dedup}_{\text{lazy}} \ [d; k; n] \). The precondition requires that the lazy collection \( k \) is safe between index 0 and \( n \), that it returns a value that is not the dummy element, and that satisfies a given postcondition \( K \). A call to \( \text{dedup}_{\text{lazy}} \) returns a location \( \ell \) and guarantees the existence of \( \bar{v} \) and \( \bar{w} \) such that \( \bar{v} \) contains \( n \) elements and \( \bar{w} \) is a deduplicated version of \( \bar{w} \). The postcondition then asserts that the returned location \( \ell \) points to \( \bar{w} \), and that for every value \( v \) in \( \bar{v} \), the assertion \( K v \) holds.

7 MECHANIZATION

All our results are mechanized in the Coq proof assistant [Moine et al. 2023b] using Iris [Jung et al. 2018] and its dedicated Proof Mode [Krebbers et al. 2018]. Rounding and excluding comments, the definition of the language takes 1200LOC, the proofs of the two logics and their soundness theorems, 4600LOC, and the verification of case studies 3700LOC. We provide tactics to be used while reasoning with the two logics, and automation to DisLog+ thanks to the Diaframe library [Mulder et al. 2022].

8 RELATED WORK

**Disentanglement.** There has been a variety of work on disentanglement [Arora et al. 2021, 2023; Guatto et al. 2018; Raghunathan et al. 2016; Westrick 2022; Westrick et al. 2022, 2020]. This work focuses on dynamic techniques that exploit disentanglement for improved efficiency, especially for parallel memory management. In particular, Arora et al. [2021] developed a provably efficient memory manager for functional programs based on disentanglement, and Arora et al. [2023] extended this approach to support unrestricted effects by accounting for the cost of entanglement. These works rely on disentanglement for efficiency and scalability, and leave the task of reasoning about disentanglement to the programmer. The first formal definition for disentanglement was given by Westrick et al. [2020] using traces of memory operations, and Westrick et al. [2022] developed a semantics which detects entanglement during execution. Our semantics for disentanglement is similar in the sense that it becomes stuck when entanglement occurs. In this context, the logics developed in this paper statically verify that execution never becomes stuck.

**Linearity and Concurrency.** Our “plain vanilla” DisLog+ (i.e., without fractional write-only assertions and objectivity lemmas) is related to reasoning approaches establishing race freedom by a linear treatment of resources. These approaches comprise type systems for the \( \pi \)-calculus [Igarashi and Kobayashi 2001, 2004] as well as session type systems [Balzer and Pfennig 2017; Caires et al. 2016; Jacobs et al. 2022; Lindley and Morris 2015; Toninho et al. 2013]. The latter are based on a Curry-Howard correspondence established between linear logic and the session-typed
π-calculus [Caires and Pfenning 2010; Wadler 2012]. Most closely related to our work in terms of employed techniques is the work by Jacobs et al. [2022], which mechanizes safety of a session-typed language in Coq, where safety encompasses freedom of memory leaks and deadlocks. The authors introduce the notion of a connectivity graph, which is acyclic by construction due to linearity, and use concurrent separation logic to prove acyclicity-preservation graph transformations. Our work, in contrast, is not confined to a linear setting.

Separation Logics. Multiple Iris-based concurrent separation logic were developed. Among them, logics targeting weak-memory models inspired DisLog+, namely iGPS [Kaiser et al. 2017], iRC11 [Dang et al. 2020] and Cosmo [Mével et al. 2020]. Indeed, they all build a high-level logic on top of a low-level logic using monotonicity arguments. In their case, assertions are monotonic predicates over the view of the memory: assertions remain valid even after observing additional memory events. In their case, the view ordering of the memory is a pure assertion. We generalize their approach to a pre-order within iProp. Moine et al. [2023a] present a separation logic to reason about heap space for a sequential language with garbage collection. Their language is similar to the sequential subset of DisLang. In particular, they also make the difference between top-level functions and heap-allocated closures. Disentanglement is closely related to garbage collection: disentanglement ensures in particular that locations occurring in the program are always safe to read for a task-local garbage collector: this is reminiscent of the free variable rule [Felleisen and Hieb 1992]. Outside the Iris world, Fu et al. [2010] present a concurrent separation logic with temporal reasoning. Contrary to them, our notion of time only relates to the pre-order induced by the fork-join structure of the program.

9 CONCLUSION AND FUTURE WORK

Disentanglement is an important property for parallel performance, but prior work leaves the challenge of reasoning about disentanglement to the programmer. We address this challenge by presenting DisLog, the first program logic to formally verify that a program is disentangled. Additionally, we present DisLog+, which allows for mostly standard separation logic proofs and offers proofs of disentanglement “for free” for many programs. Using these logics, we prove disentanglement for a number of examples, including several lock-free data structures. Our experience with DisLog and DisLog+ is that the effort required to prove disentanglement is often small and can be confined to the daring parts of the program. In future work, we plan to develop a type system to automatically infer disentanglement where possible. We hope that a semantic type soundness approach making use of DisLog could be used to prove such a system sound.

DATA AVAILABILITY STATEMENT
The DisLog and DisLog+ logics, their soundness proofs and all our case studies are mechanized (§7). This mechanization is recorded in an artifact available on Zenodo [Moine et al. 2023b].

ACKNOWLEDGMENTS
We would like to thank Clément Allain and Arthur Charguéraud for insightful discussions, Ike Mulder for his help with Diaframe, and the anonymous reviewers for their helpful feedback. This research was supported by NSF grants CCF-1901381, CCF-2115104, CCF-2119352, and CCF-2107241, and also by a gift from Intel.
