A Hierarchical Resource Reservation Algorithm for Network Enabled Servers

E. Caron , F. Desprez , F. Petit , V. Villain January 2003

Abstract

This paper presents the application of the PIF algorithm to a Network Enabled Server environment. Hierarchical scheduling is applied to improve the scalability of the overall architecture and fault tolerance problems are addressed using timers. The simulation shows that gains can be obtained using such a platform over single scheduler approaches.

Keywords: Distributed computing, hierarchical scheduling, Network Enabled Servers.

Résumé

Cet article présente l'algorithme du PIF dans un cadre de serveurs de calcul distribués. L'extensibilité de la plate-forme ainsi que des mécanismes de tolérance aux pannes sont mis en œuvre via un ordonnancement hiérarchique. Le gain de performances est mis en évidence par un outil de simulation.

Mots-clés: Calcul distribué, Ordonnancement hiérachique, Serveurs de calcul

1 Introduction

Huge problems can now be computed over the Internet with the help Grid Computing Environments [13]. Several approaches co-exist like object-oriented languages, message passing environments, infrastructure toolkits, Web-based, and global computing environments, . . . The Remote Procedure Call (RPC) [16] paradigm seems also to be a good candidate to build Problem Solving Environments (PSE) for different applications on the Grid. Indeed, it allows to hide complicated resource allocation and job distribution strategies to the user. Moreover, parallelism can be hidden using parallel servers. Several environments following this approach exist, like NetSolve [3], Ninf [17], DIET [5], NEOS [18] or RCS [2]. They are commonly called Network Enabled Server (NES) environments [16]. The overall architecture of a classical Network Enabled Server System is given in Figure 1. NES environments usually have five different components. Clients (C in Figure 1) that submit problems they have to solve to Servers (S), a Database (D) that contains (static and dynamic) information about software and hardware resources, a Scheduler (Sched) that chooses an appropriate server depending on the problem sent and the information contained in the database, and finally Monitors (M) that acquire information at run-time about the status of the computational resources.

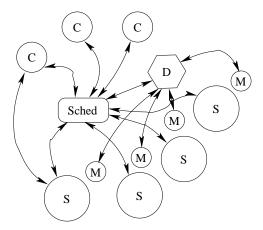

Figure 1: General architecture of a Network Enabled Server.

Most of the environments previously cited have a centralized scheduler which can become a bottleneck when many clients try to access several servers with a large number of requests. Moreover as networks are highly hierarchical, the location of the scheduler has a great impact on the performance of the overall architecture. Thus we have designed DIET [5], a NES environment that focuses on offering such a service at a very large scale using a hierarchical set of schedulers. This environment is described in Sec-

tion 2. The scheduling algorithm has to take into account the hierarchy of the platform and the possibility of simultaneous requests coming from different clients and filling the different stages of the tree. Finally, fault can occur at the server or at the scheduler level.

Few work exist about scheduling in NES environments. In [22], the authors present an algorithm that uses dead-lines on requests to load balance the work among the servers. However, the scalability of the overall architecture is not studied. The authors of [1] present H-SWEB, a hierarchical approach for the scheduling of HTTP requests across clusters of servers. Hierarchical scheduling can also be applied to shared memory machines like in [10] or distributed memory machines [24] for the scheduling of independent jobs. Finally, in [20], the authors present a 2 level scheduler for metacomputing systems.

Resource reservation is also a problem in such environments when different servers are share by different clients. Several requests can simultaneously be sent in the hierarchy and servers can be chosen by different schedulers at the same time. Our paper thus presents the extension of an existing algorithm (PIF [4, 9, 8, 21]) used for resource reservation in a NES environment using a hierarchy of schedulers. This algorithm can also take into account faults at different levels using timers.

The rest of the paper is organized as follows. The first section present the DIET environment and its hierarchical architecture. Section 3 describes the PIF algorithm and the extensions we added for fault tolerance. Finally and before some concluding remarks, we present a validation of the algorithm and the hierarchical approach using simulations.

2 DIET Overview

DIET [5] is built upon Computational Resource Daemons and Server Daemons. The scheduler is scattered across a hierarchy of Agents. Figure 2 shows the hierarchical organization of DIET. A Client is an application that uses DIET to solve problems in a RPC mode. Different kinds of clients should be able to connect to DIET from a web page, a PSE such as Matlab or Scilab, or from a program written in C or Fortran.

The hierarchy of scheduling agents is made of some Master Agent (MA), several Agents (A), and Local Agents (LA).

A Master Agent is the entry point of our environment and thus receives computation requests from clients attached to it. These requests refer to some DIET problems that can be solved by registered servers. This problems can be listed on a reference web page. A client can be connected to an MA by a specific name server or a web page which stores the various MA locations.

Then the MA collects computation abilities from the servers and chooses the best one according to some scheduling heuristics (dead-line scheduling, shortest completion time first, minimization of the requests throughput, ...). A reference to the server chosen is sent back to the client.

A Master Agent relies on a hierarchy of agents to gather information and scheduling decisions. An **Agent** aims at transmitting requests and information between MAs and LAs. A **Local Agent** (LA) aims at transmitting requests and information between Agents and several servers. The information stored on an Agent is the list of requests and the number of servers that can solve a given problem and information about the data distributed in this subtree. Depending on the underlying network topology, a hierarchy of Agents may be deployed between an MA and the LAs. The scheduling and the gathering of information is distributed in the tree.

Computations are done by servers in front of which we have **Server Daemons** (**SeD**). A SeD encapsulates a computational server. For instance it can be located on the entry point of a parallel computer. The information stored on an SeD is a list of the data available on its server (with their distribution and the way to access them), the list of problems that can be solved on it, and all information concerning its load (memory available, number of resources available, . . .). A SeD declares the problems it can solve to its parent LA. A SeD can give performance prediction for a given problem using the performance evaluation module (FAST [19]).

Finally, computation in interactive mode are executed by a federation of **Computational Resource Daemons** located on the different processors of a parallel server. A batch approach can also be used and the computation requests are sent to the batch system directly by the Server Daemon.

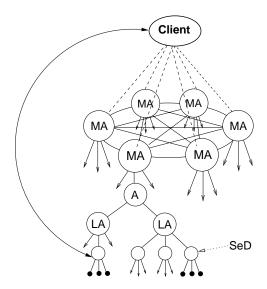

Figure 2: Hierarchical organization of DIET.

DIET includes a module called FAST (Fast Agent's System Timer) [19]

to provide different information needed by the agents. FAST is a software package allowing client applications to get an accurate forecast of routines needs in terms of completion time, memory space and communication costs, as well as of current system availability (memory, machine load), and communication speeds. For sequential routines, we developed a tool [12] that benchmarks routines in time and space and then fits the resulting data by polynomial regression. Concerning parallel versions, analytical expressions were extracted from code studies to give a theoretical model [6]. The forecast of the communication time between different elements of the hierarchy is allowed by the use of NWS (Network Weather Service) [25]. NWS sensors are placed on every node of the hierarchy to collect resource availabilities, which are then used by FAST.

DIET is also designed to take into account the data location during scheduling. Data are kept as long as possible on (or near to) the computational servers on which they have been computed to minimize transfer times. This kind of optimization is mandatory to obtain performance on a wide-area network.

Finally, NES environments like Ninf and NetSolve are implemented using a classic socket communication layer. Nevertheless several problems to this approach have been pointed out such as the lack of portability or the limitation of opened sockets. Distributed object environments, such as Java, DCOM or Corba [14] have proven to be a good base for building applications that manage access to distributed services. They provide transparent communications in heterogeneous networks, but they also offer a framework for the large scale deployment of distributed applications. Moreover, Corba systems provide a remote method invocation facility with a high level of transparency. This transparency should not dramatically affect the performance, communication layers being well optimized in most Corba implementations [11]. Thus, Corba has been chosen as a communication layer in DIET.

In the next section, we design the hierarchical and distributed scheduler used in DIET. The scheduler is implemented using the *Propagation of Information with Feedback* scheme (the PIF scheme, for short). Chang [8] and Segall [21] independently defined the concept of PIF (also called *wave propagation*). The solutions to these basic problem can then be used as the basis for the solution to a wide class of problems in distributed computing, e.g., distributed infimum function computations (leader election), termination detection, and synchronization (see [23] for these algorithms). The PIF scheme was also studied in the area of *self-stabilization*, e.g., [4, 9]. Although this paper did not tackle the problem the paradigm of self-stabilization, this desirable property would be considered in future works.

In the first subsection, we quickly recall how the PIF scheme works on a tree network and we describe how we use the PIF scheme to deal with requests submitted to the scheduler. Fault tolerance mechanisms are also discussed.

3 The Distributed Scheduling Algorithm

3.1 Description of the PIF Algorithm in Tree Networks

Let us quickly review the well-known PIF scheme on tree structured networks. The PIF scheme works in two phases. The first phase is called the broadcast phase. Starting from an initial configuration where no message has yet been broadcast (Figure 3 (i)), the root of the tree network initiates the broadcast phase by broadcasting a message m to its descendants. Then, the descendants of the root (except the leaf processors) participate in this phase by forwarding the broadcast message to their descendants (Figure 3 (ii)). Basically, during the broadcast phase, m is propagated in the whole tree. Once the leaves are reached by the broadcast phase (i.e., m), since the leaves have no descendant, they notify the termination of the broadcast phase by sending a feedback message to their parent. This initiates the feedback phase (Figure 3 (iii)). When the parent receives the feedback messages from all its descendants, it sends a feedback message to its own parent, and so on. So, eventually, the root receives a feedback message from all its descendants. This marks the end of the feedback phase (Figure 3 (iv)). In other words, all nodes acknowledged the receipt of m to the root.

We now describe how the PIF scheme is used to proceed a request from a client to a DIET server.

3.2 Application of the Algorithm to DIET

Each client is assigned with a unique MA. The client sends the request to the corresponding MA which initiates a broadcast phase by propagating the request toward each available agent in its subtrees. So, each LA connected in the hierarchy eventually receives the client's request and the broadcast phase ends on the servers. (Figure 4 (1.)).

On each server, the FAST module included into the SeD computes the resources required to serve the request and the expected computation time. If a server is able to fulfill the request, FAST makes the reservation for the required resources. In any case, every server initiates the feedback phase by returning the forecast of the execution time to its parent LA (Figure 4 (2.)).

According to the feedback phase synchronization, the LA waits for the FAST response from each of its descendant and chooses the identity of the most "appropriate" server (or list of servers for scheduling purposes), i.e., the fastest or the cheapest one(s). Next, following the feedback phase description, it sends the result to his parent node and releases the servers which were not selected (using the PIF scheme in the corresponding subtree). Stage by

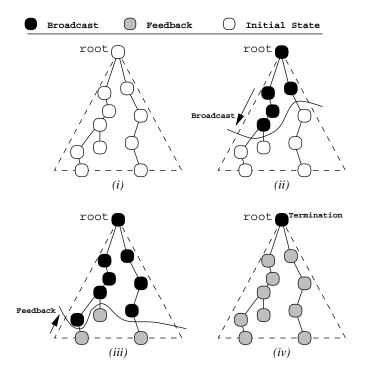

Figure 3: The PIF scheme.

stage, and following the same scheme, the MA eventually receives the selected server ID(s) (Figure 4 (3. and 4.))

Finally, the MA sends the server ID(s) to the client which in turn contacts the server(s) to initialize the computation. Then, data are sent. The server(s) is now able to solve the requested problem. When the computation is done, the results are sent back to the client. All resources used to fulfill the request are released. (Figure 4 (4.))

Two problems can occur with the algorithm previously presented. If every agent waits until all its son nodes have answered, and if some part of the hierarchy has crashed, we can have a infinite wait. Moreover with one mechanism of reservation of resource, DIET must be able to process cross requests, i.e. requests sent by different clients for the same resource. In the next section, we explain how to deal with both problems.

3.3 Fault Tolerance Mechanisms

Processing of a Server Failure

In order to take into account servers failure, we added a time-out at the LA level. The resulting algorithm for the server front-end (LA) is given in Algorithm 1.

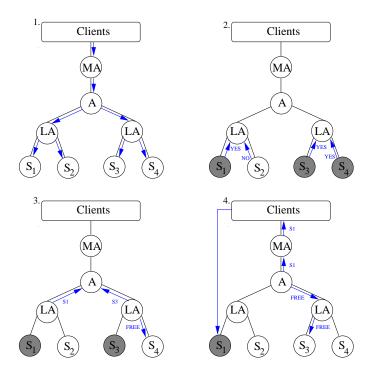

Figure 4: PIF algorithm execution to proceed a request from a client to a DIET server. (The gray circle corresponding to locked resource)

The value of the timer α represents the time during which DIET waits for the first server's answer. If no server responds, the LA replies to its father that no server is available for the current request. If at least one server answers, a second timer equal to β is started. The purpose of this timer is to fix a compromise between the response time of the scheduler and the aggregation of the answers of different servers. Without this timer, one does not obtain the most effective server but the one which answered the most quickly to FAST. α and β depend on the number of servers. We can further optimize the response time by decreasing the timer β when the number of server responses increases.

Remark that the **Ireceive** call is an asynchronous function. If a server is not ready to answer one chooses the following according to a ring.

Processing of an Agent Failure

The failure of any agent in the hierarchy could also lead to an infinite wait and the lost of a branch of the scheduler tree. To avoid such wait, we set an other timer σ which depends of the depth of the tree (see Algorithm 2).

In this case, the Ireceive function can be seen like as synchronous. However, it can still be interrupted by the time-out σ .

Algorithm 1 LA algorithm using a time-out

```
timer = 0
time out = \alpha
current server=0
response=0
while ((timer<time out) OR (response! =nb server)) do
  if Memory response[current server] != TRUE then
    if (Ireceive(FAST\_INFORMATION, S_{current server})) == OK then
      timer = 0
      time out = \beta
      response++
      Memory response[current server] = TRUE
    end if
  end if
  current server++
  if current server == nb server+1 then
    current server = 0
  end if
end while
```

Algorithm 2 Agent algorithm using a time-out

```
\begin{array}{l} {\rm timer} = 0 \\ {\rm time\_out} = \sigma \\ {\rm \ for \ all \ leaf \ of \ the \ current \ agent \ do} \\ {\rm \ \ while \ (Ireceive(SCHEDULER\_INFORMATION, Agent}_{leaf}) \ == \ OK)} \\ {\rm OR \ (timer<time\_out) \ do} \\ {\rm \ \ nothing} \\ {\rm \ \ end \ while} \\ {\rm \ \ end \ for} \end{array}
```

Note that no Agent knows the numbers of server (in contrast to an LA). So, it seems difficult to design an algorithm using two time-out (as for the LA algorithm) because no way allows to compute the second time-out.

Concurrent Requests Processing

From the client point of view, the resource (server) allocated by the MA has to be reserved. Indeed, if two clients send two requests and the chosen server is the same (because this server is available during the FAST step), a conflict can occur. When the second client asks the server for the resolution of its request, the server can be already working on the first client's request.

To avoid this problem, we introduce a time-stamp mechanism in the FAST calls than make the resource reservation sequential. The drawback of this

solution is the following. The capacities of the server can be underestimated when resources are released. We lose in precision for the forecast but gain of system stability for the client.

3.4 Experiments

Simulation

SIMGRID [15] is a simulation toolkit based on SIMGRID [7]. SIMGRID provides an excellent framework for setting up a simulation where decisions are taken by a single scheduling process. However, in metacomputing systems like DIET, the scheduler is distributed on each agent without a global scheduling mechanism. Moreover, the number of schedulers is not fixed in advance. New agents can be added at runtime and different scheduling politics can be used. In a hierarchical structure, the location of the schedulers and the cooperation between them have a great impact on the performance of the overall architecture. SIMGRID2 allows to link an execution thread to scheduler. Thus, each scheduler is not static and can take a decision according to the current task or the state of the system. It is not required to know in advance where each task must be sent. In DIET, the scheduler politic depends upon the measured performance of the servers.

To simulate DIET in SIMGRID2, we made a model of each DIET process as a SIMGRID2 process. In order to understand the complete execution, Figure 5 gives an overview of communications required by each component.

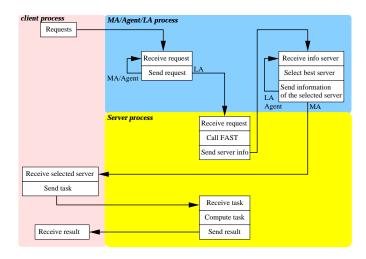

Figure 5: Process execution on a simple DIET environment.

Impact of the Hierarchy

The first simulation shows the impact of the hierarchy of agents. For the sake of simplicity, we used an homogeneous network similar to Fast Ethernet and each server depends on the same CPU. Three kinds of DIET architectures have been defined to manage 64 servers. Table 1 describes the amount of different DIET components. The duration of each task is 100 seconds with no other load. Indeed, SIMGRID2 computes the running time using the CPU speed of the host (10 Mflops/s) and the amount of processing (in Mflop) needed to process the task on a server (1000 Mflop). In this simulation no reservation system is taken into account.

Hierarchical Level	MA	Agent	$\mathbf{L}\mathbf{A}$	Server
Level 1	1	2	4	16
Level 2	1	6	8	8
Level 3	1	14	16	4

Table 1: Amount of elements used to manage 64 servers. The column "Server" is the amount of servers depending on one LA.

Figure 6 shows the impact of the hierarchical model. Two factors explain this result. We do not have to prove that the broadcast on a tree is better than a straightforward round robin algorithm to find the best server available. The second factor depends on the ratio between the time to send a request and the time to launch the computing task. Due to simultaneous requests send, a server gives the same response to a set of requests. Thus several tasks choose the same server. When the depth of the hierarchy increases, the response time increases in the same manner and the forecast error of resource availability decreases. The computing step begins after the end of the resource search step. Thus the forecasting system can take into account the result of computing more quickly. Moreover, this simulation shows the interest of reservation system previously described in Section 3.

Impact of the Reservation Mechanism System

The reservation of resource implies a cost. Servers are indeed locked and forecast is underestimated during a short time. However, when we take into account the reservation system, the scheduling can be more efficient as the agents are aware that several servers have been reserved and thus they can be potentially used by clients. The second experiment allows to evaluate the mechanism reservation impact over execution time from 10 to 70 tasks. We simulate DIET architecture with and without a reservation mechanism system. In this simulation, each task requires 10000 Mflops (1000 seconds in a stand-alone mode on a server). Figure 7 shows how it is important to

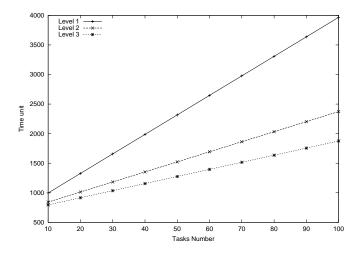

Figure 6: Evaluation of three hierarchical levels.

include a reservation mechanism. This approach overloads less the whole set of servers.

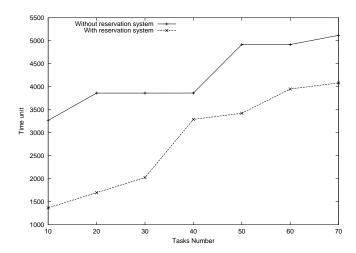

Figure 7: Evaluation of scheduler with reservation system and without in hierarchical platform (level 1).

4 Conclusion and Future Work

In this paper, we have presented the application of the PIF algorithm to a Network Enabled Server environment to obtain an efficient resource reservation on the different servers available. Hierarchical scheduling is applied to improve the scalability of the overall architecture when a large number of requests are sent to the NES environment. Fault tolerance problems are addressed using timers. The simulation shows that gains can be obtained using a hierarchical platform and that the PIF algorithm is efficient despite the number of messages sent to the system. The accuracy of the performance evaluation is also improved thanks to the reservation of servers.

Our future work consists in adding scheduling heuristics on each server to be able to manage tasks with data dependences. Moreover, as our environment allows to leave the data in place after the computation of one request, we need to add specific redistribution schemes between the servers. About fault tolerance, even if the presented approach avoids infinite waits, we need also to be able to restart agents or servers when a failure occurs. We also would like to include the desirable property of self-stabilization in order to tolerate transient faults.

Finally, we are currently porting several applications on the DIET environment that may raise specific problems due to their computation and data distribution needs.
