Multiplication by an Integer Constant

Vincent Lefèvre

Abstract: We present and compare various algorithms, including a new one, allowing to perform multiplications by integer constants using elementary operations. Such algorithms are useful, as they occur in several problems, such as the Toom-Cook-like algorithms to multiply large multiple-precision integers, the approximate computation of consecutive values of a polynomial, and the generation of integer multiplications by compilers.

Key-words: integer multiplication, addition chains

Multiplication par une constante entière

Résumé : Nous présentons et comparons divers algorithmes, dont un nouveau, permettant d'effectuer des multiplications par des constantes entières à l'aide d'opérations élémentaires. De tels algorithmes sont utiles, car ils interviennent dans plusieurs problèmes, comme les algorithmes du style Toom-Cook pour multiplier des entiers à grande précision, le calcul approché de valeurs consécutives d'un polynôme et la génération de multiplications entières par les compilateurs.

Mots-clés : multiplication entière, chaînes d'additions

1 Introduction

The multiplication by integer constants occurs in several problems, such as:

- algorithms requiring some kind of matrix calculations, for instance the Toom-Cook-like algorithms to multiply large multiple-precision integers [7] (this is an extension of Karatsuba's algorithm [3]),

- the fast *approximate* computation of consecutive values of a polynomial [6] (we can use an extension of the finite difference method [4] that needs multiplications by constants),

- the generation of integer multiplications by compilers, where one of the arguments is statically known (some processors do not have an integer multiplication instruction, or this instruction is relatively slow).

We look for an algorithm that will generate code to perform a multiplication by an integer constant n, using left shifts (multiplications by powers of two), additions and subtractions. The other instructions available on processors, like right shifts, could be taken into account, but will not be used in the following.

We assume that the constant n may have several hundreds of bits. If it is large enough (several thousands of bits?), then fast multiplication algorithms of large integers can be used, without taking into account the fact that n is a constant.

To make the study of this problem easier, we need to choose a model that is both simple and close to the reality. We can assume that all the elementary operations (shifts by any number of bits, additions and subtractions) require the same computation time. This problem is much more difficult than the well-known *addition chains* problem [4]. A detailed formulation is given in Section 2.

The multiplication by an integer constant problem has already been studied for compilers, but for relatively small constants (on at most 32 or 64 bits). We do not know any algorithm that can generate optimal code in a reasonable time; thus we use heuristics.

A first (naive) heuristic will be described in Section 3.1. But most compilers implement an algorithm from Robert Bernstein [1] or a similar algorithm (taking into account the features of the target processor). In his article, Bernstein gives an implementation of his algorithm, but unfortunately with typos. Then Preston Briggs presented a corrected implementation in [2], but his code posted in 1992 to the `comp.compilers`[1] *newsgroup* is also broken! This implementation is shortly described in Section 3.2; I have rewritten it in order to perform some comparisons in Section 5.

The complexity (in time) of Bernstein's algorithm is an exponential function of the constant size. It is fast enough for small constants, but much too slow for larger constants. For instance, even 64-bit constants may require more than one second on a 400 MHz G4 PowerPC, which may be too much for a compilation. I have found and implemented a completely different algorithm, that is fast enough for constants having several hundreds bits. It is presented in [5] and [6]. Section 3.3 gives a description and an improvement of

---

[1]http://compilers.iecc.com/comparch/article/92-10-074

this algorithm, which also allows to generate code to multiply a single number by several constants.

All these algorithms are compared in Section 5, both for the time complexity and the quality of the generated code.

2   Formulation of the Problem

A number x left-shifted k bit positions (i.e., x multiplied by 2^k) is denoted $x \ll k$, and the shift has a higher precedence than the addition and the subtraction (contrary to the precedence rules of some languages, like C or Perl). We assume that the computation time of a shift does not depend on the value k, called the *shift count*. Nowadays, this is true for many processors. Concerning the multiple precision, a shift consists of a shift at the processor level (where the shift count is bounded by the register size) and a shift by an integer number of words; thus, in the reality, a shift would be faster when k is an integer multiple of the register size. But it is difficult to take into account such considerations just now; we prefer to choose a simple model, that does not depend on the context.

In fact, in the algorithms we will describe, shifts will always be associated with another operation (addition or subtraction), and in practice, we will work with odd numbers only: shifts will always be delayed as much as possible. For instance, instead of performing $x \ll 3 + y \ll 8$, we will choose to perform $(x + y \ll 5) \ll 3$. This is a bit similar to floating-point operations, where a shift corresponds to an exponent change, but where shifts are actually performed only in additions and subtractions.

Thus the elementary operations will be additions and subtractions where one of the operands is left-shifted by a fixed number of bits (possibly zero, but this will never occur in the algorithms presented here), and these operations will take the same computation time, which will be chosen to be a time unit. Assuming that the operations $x + y$ and $x + y \ll k$ with $k > 0$ take the same computation time is debatable but reasonable. Indeed, with some processors (for instance, most ARM's), such operations do take the same computation time (1 clock cycle). And we recall that in multiple precision, the computation time does not depend on the number of word shifts: the condition is not the fact that k is zero or not, but the fact that k is an integer multiple of the register size or not. Moreover, note that these assumptions modify the computation time by a bounded factor; as a consequence, a complexity of the form $O(F(n))$ is not affected by these assumptions.

Let n be a nonnegative odd integer (this is our constant). A finite sequence of nonnegative integers $u_0, u_1, u_2, \ldots, u_q$ is said to be *acceptable* for n if it satisfies the following properties:

- initial value: $u_0 = 1$;

- for all $i > 0$, $u_i = |s_i\, u_j + 2^{c_i}\, u_k|$, with $j < i$, $k < i$, $s_i \in \{-1, 0, 1\}$ and $c_i \geq 0$;

- final value: $u_q = n$.

Thus, an arbitrary number x being given, the corresponding code iteratively computes $u_i x$ from already computed values $u_j x$ and $u_k x$, to finally obtain nx. Note that with this

formulation, we are allowed to reuse any already computed value. Therefore some generated codes may need to store temporary results. Moreover, the absolute value is only here to make the notations simpler and no absolute value is actually computed: if $s_i = -1$, we always subtract the smaller term from the larger term.

The problem is to find an algorithm that takes the number n and that generates an acceptable sequence $(u_i)_{0 \le i \le q}$ that is as short as possible; q is called the *quality* (or *length*) of the generated code (it is the average computation time when this code is executed under the condition that each instruction takes one time unit). But this problem is very difficult (`comp.compilers` contributors conjecture that it is NP-complete). Therefore we need to find heuristics.

Note: we restricted to nonnegative integers. We could have changed the formulation to accept negative integers (by removing the absolute value and letting the choice between u_j and u_k to apply the sign s_i), but the problem would not be very different. We can also extend the formulation to take into account even constants; then, we will allow a free left shift to be performed at the end (see the above paragraph on delayed shifts).

Also note that if c_i and s_i are never zero (this will be the case in the considered heuristics), then the u_i are all odd.

3 Algorithms

3.1 The Binary Method

The simplest heuristic consists in writing the constant n in binary and generating a shift and an addition for each 1 in the binary expansion (taking the 1's in any order): for instance, consider $n = 113$, that is, we want to compute $113x$. In binary, 113 is written 1110001_2. If the binary expansion is read from the left, the following operations will be generated:

$$
\begin{aligned}
3x &\leftarrow & x \ll 1 &+& x \\
7x &\leftarrow & 3x \ll 1 &+& x \\
113x &\leftarrow & 7x \ll 4 &+& x.
\end{aligned}
$$

The number of elementary operations q is the number of 1's in the binary expansion, minus 1. For random m-bit constants with uniform distribution, the average number of elementary operations, denoted q_{av}, is asymptotically equivalent to $m/2$.

This method can be improved using Booth's recoding, which consists in introducing signed digits (-1 denoted $\overline{1}$, 0 and 1) and performing the following transform as much as necessary:

$$
0\underbrace{1111\ldots1111}_{k \text{ digits}} \rightarrow 1\underbrace{0000\ldots000}_{k-1 \text{ digits}}\overline{1}.
$$

This transform is based on the formula:

$$
2^{k-1} + 2^{k-2} + \cdots + 2^2 + 2^1 + 2^0 = 2^k - 1.
$$

This allows to reduce the number of nonzero digits from k to 2. As a digit 0 is transformed into a digit 1 on the left, it is more interesting to read the number from right to left: thus, the created 1 can be used in the possible next sequence of 1's. For instance, 11011 would be first transformed into $1110\bar{1}$, then into $100\bar{1}0\bar{1}$. However, note that in general, there are several representatives having the same number of nonzero digits.

With the above example, 113 is written $100\bar{1}0001_2$. Thus, Booth's recoding allows to generate 2 operations only, instead of 3:

$$
\begin{array}{rcrcl}
7x & \leftarrow & x \ll 3 & - & x \\
113x & \leftarrow & 7x \ll 4 & + & x.
\end{array}
$$

The number of elementary operations q is the number of nonzero digits (1 and $\bar{1}$), minus 1. And one can also prove that $q_{\mathrm{av}} \sim m/3$.

3.2   Bernstein's Algorithm

Bernstein's algorithm is based on arithmetic operations; it doesn't explicitly use the binary expansion of n. It consists in restricting the operations to $k = i - 1$ and $j = 0$ or $i - 1$, $s_i \neq 0$ and $c_i \neq 0$ in the formulation, and one of the advantages is that it can be used with different costs for the different operations (the addition, the subtraction and the shifts). It is a *branch-and-bound* algorithm, using the following formulas:

$$
\begin{array}{rcl}
\mathrm{Cost}(1) & = & 0 \\
\mathrm{Cost}(n \text{ even}) & = & \mathrm{Cost}(n/2^c \text{ odd}) + \texttt{ShiftCost} \\[2mm]
\mathrm{Cost}(n \text{ odd}) & = & \min \left\{
\begin{array}{l}
\mathrm{Cost}(n+1) + \texttt{SubCost} \\
\mathrm{Cost}(n-1) + \texttt{AddCost} \\
\mathrm{Cost}(n/(2^c+1)) + \texttt{ShiftCost} + \texttt{AddCost} \\
\mathrm{Cost}(n/(2^c-1)) + \texttt{ShiftCost} + \texttt{SubCost}
\end{array}
\right.
\end{array}
$$

where the last two lines apply each time $n/(2^c + 1)$ (resp. $n/(2^c - 1)$) is an integer, c being an integer greater or equal to 2.

Note that if n is odd, then $n + 1$ and $n - 1$ are even, therefore adding or subtracting 1 is always associated with a shift. As a consequence, assuming that the add and subtract costs are equal, we get back to our formulation.

The minimal cost and an associated sequence are searched for by exploring the tree. But there will be redundant searches. A first optimization consists in avoiding them with a memoization: results (for odd numbers only) are recorded in a hash table.

Sometimes, deep in a search, the cost associated with the partial path becomes greater than the current cost[2]; thus it is clear that this is a fruitless path, and it is useless to go deeper: we prune the tree. Moreover, in order to avoid using fruitless paths too often, each time we come across a node, a lower bound of its cost is associated with it.

---

[2]This cost is initialized with an upper bound, for instance by using the binary method, and it is updated each time a cheaper path is found.

The average time complexity seems to be exponential. The generated code cannot be longer than the one generated by the binary method, since the binary method corresponds to one of the paths in the search tree. But we do not know much more. Anyway, because of its complexity, this algorithm is too slow for large constants. This is why we will study new algorithms in the next section.

3.3   A Pattern-based Algorithm

3.3.1   A Simple Algorithm

This algorithm is based on the binary method: after Booth's recoding, we regard the number n as a vector of signed digits 0, $+1$, -1, denoted respectively `0`, `P` and `N` (and sometimes, 0, 1 and $\overline{1}$). The idea, that is recursively applied, is as follows: we look for repeating digit-patterns (where `0` is regarded as a blank), to make the most nonzero digits (`P` and `N`) disappear in one operation. To simplify, one only looks for patterns that repeat twice (though, in fact, they may repeat more often).

For instance, the number 20061, 100111001011101_2 in binary, which is recoded to `POPOONOPONOONOP`, contains the pattern `POOOOOOPON` twice: the first one in the positive form and the second one in the negative form `NOOOOOONOP`. Thus, considering this pattern allows to make 3 nonzero digits (contrary to one with the binary method) disappear[3] in one operation; thus we have reduced the problem to two similar (but simpler) problems: computing the pattern `POOOOOOPON` and the remainder `OOPOOOOOOOOOOOO`. This can be summarized by the following double addition:

```
      POOOOOOPON
  -         POOOOOOPON
  + OOPOOOOOOOOOOOO
    ------------------
      POPOONOPONOONOP
```

On this example, 4 operations are obtained (`POOOOOOPON`, 515 in decimal, is computed with 2 operations thanks to the binary method),

$$
\begin{array}{rcccc}
129x & \leftarrow & x \ll 7 & + & x \\
515x & \leftarrow & 129x \ll 2 & - & x \\
15965x & \leftarrow & 515x \ll 5 & - & 515x \\
20061x & \leftarrow & x \ll 12 & + & 15965x
\end{array}
$$

whereas Bernstein's algorithm generates 5 operations, that is one more than our algorithm.

Now, it is important to find a good repeating pattern quickly enough. Let us give some definitions. A *pattern* is a sequence of nonzero digits up to a shift (for instance, `PONOON` and `PONOONO` are the same pattern) and up to a sign: if we invert each nonzero digit, we obtain

---

[3]or appear — this depends on the way we regard the algorithm.

the pattern under its opposite form (for instance, `PONOON` becomes `NOPOOP`). The number of nonzero digits of a pattern is called the *weight* of the pattern; the weight will be denoted w. We look for a pattern having a maximal weight. To do this, we take into account the fact that, in general, there are much fewer nonzero digits than zero digits, in particular near the leaves of the recursion tree, because of the following relation: $w(\text{parent}) = 2\,w(\text{child 1}) + w(\text{child 2})$, child 1 being the pattern; child 2 is called the *remainder*. The solution is to compute all the possible distances between two nonzero digits, in distinguishing between identical digits and opposite digits. This gives an upper bound on the pattern weight associated with each distance[4]. For instance, with `POPOONOPONOONOP`:

operation	distance	upper bound	weight
$\left|u_j - 2^2 u_k\right|$	2 (P-N / N-P)	3	2
$\left|u_j - 2^5 u_k\right|$	5 (P-N / N-P)	3	**3**
$\left|u_j + 2^7 u_k\right|$	7 (P-P / N-N)	3	2

The distances are sorted according to the upper bounds, then they are tested one after the other until the maximal weight and a corresponding pattern are found.

The complexity of the whole algorithm is polynomial, in $O(m^3)$ in the worst case, where m is the constant's length. Indeed, there are at most $m' - 1$ pattern searches (i.e., recursive calls), where m' is the number of nonzero digits ($m' \leq m$), and each pattern search has a complexity in $O(m^2)$. After testing the current implementation on random values, we have found that the average complexity of this implementation seems to be in $\Theta(m^2)$, or a close function.

3.3.2 Possible Improvements

Our algorithm can still be improved. Here are a few ideas proposed in [6]:

- We can look for subpatterns common to different branches of the recursion. For instance, let us consider `PONONOOPONONOOOPON` and the pattern `PONON`. `PON` appears twice: in the pattern `PONON` and in the remainder `PON`; as a consequence, it can be computed only once (under the condition that `PONON` is computed in the right way, by making `PON` appear). A solution will be given in the next section.

- When looking for a repeated pattern, we can often have the choice between several patterns having the same maximal weight. Instead of choosing only one pattern, we can consider several of them, try them one after the other, and keep the shortest generated code. Ideally, we would test all the maximal-weight patterns, but we have to make sure that the complexity of the algorithm does not become exponential.

---

[4]Only an upper bound, as a same nonzero digit cannot be used in both occurrences of the pattern at the same time.

- We can consider the following transformation, which does not change the weight: `PON` ↔ `OPP` (and `NOP` ↔ `ONN`). For instance, 11010101001_2 is encoded to `PONOPOPOPOOP` by default, which gives a maximal weight of 1, therefore 5 generated operations; but the equivalent code `POONONNOPOOP` is better: with the pattern `POONOON` of weight 3, only 3 operations are generated. The drawback is the possibly exponential number of equivalent codes. Therefore it is not conceivable to always take all of them into account. We need a method allowing to quickly find the best transformations. For instance, it can be interesting, under some conditions, to perform the transformation as long as the weight of the currently considered pattern is not satisfactory; note that the number of `PON` and `NOP` (in a same constant[5]) cannot be greater than the doubled weight of the currently considered pattern. Or, once the pattern has been found, we can try to perform the transformation in order to add nonzero digits to the pattern, and therefore to increase its weight.

Using operations other than additions, subtractions and left shifts could be interesting, in particular the *logical or*, which suits the handling of binary data. But we would first have to separate positive and negative digits.

3.3.3 A New Algorithm (Common Subpatterns)

The generalization of the algorithm presented previously to the common subpattern search can be done quite naturally. In fact, we need to find an algorithm generating code for multiplying a single number by several constants at the same time, which is moreover useful when multiplying by constant matrices, for instance.

The problem is now: a set of constants written in binary using signed digits `O`, `P` and `N` being given, find a maximal-weight pattern that appears twice (either in a same constant or in two different constants). Note that if such a pattern appears more than twice, it can naturally be reused later (this was not the case of the first algorithm).

Instead of looking for a distance leading to a pattern in a binary expansion (positive integer), we look for a triple (i, j, d) where i and j are numbers identifying the two constants n_i and n_j (possibly the same, i.e., $i = j$) in the set, and d a distance (or shift count)[6], with the following restrictions for symmetry reasons:

1. $i \leq j$;

2. if $i = j$, then $d > 0$.

Once the pattern, denoted n_p, of weight greater or equal to 2 has been found, we compute the binary expansion of the new constants n_i' and n_j' (n_i' only, if $i = j$) satisfying $n_i = n_i' \pm 2^c n_\mathrm{p}$ and $n_j = n_j' \pm 2^{c-d} n_\mathrm{p}$ for some integer c (or $n_i = n_i' \pm 2^c n_\mathrm{p} \pm 2^{c-d} n_\mathrm{p}$ if $i = j$)[7], then we

---

[5]We have to be precise on this point, in the case we would want to apply these transformations in the algorithm described in Section 3.3.3; however, for this algorithm, we will consider pairs of constants and this will not change much.

[6]For instance, this is the difference between the exponents of the rightmost digit of the pattern occurrences.

[7]$\pm$ is either an addition or a subtraction where nonzero digits do not overlap.

remove n_i and n_j from the set, then add n'_i, n'_j and n_p to the set (with the exception that 0 and 1 are never added to the set, because they cannot yield a pattern). We reiterate until there are no more patterns of weight greater or equal to 2; we use the binary method for the remaining constants. We do not want to discuss the implementation details in this paper; they are left to the reader.

Now, let us illustrate this algorithm more precisely with an example: 47804853381, which is written $10110010000101100100001011001000001012$ in binary, and after Booth's recoding: `PON0N00P000P0N0N00P000P0N0N00P0000P0P`. As there is only one constant for the time being, the first step is similar to the one of the previous algorithm. We find the triple[8] $(0, 0, 11)$, the corresponding pattern is `PON0N00P`, and the remainder is `PON0N00P000000000000000000000000000P0P` (there would be other choices). The set is now:

$$\{\, \texttt{PON0N00P000000000000000000000000000P0P, PON0N00P}\,\}.$$

We find the triple $(0, 1, 29)$, the corresponding pattern is `PON0N00P` (i.e., still the same one), and the remainder is `P0P`. The set is now:

$$\{\, \texttt{P0P, PON0N00P}\,\}.$$

We find the triple $(0, 1, -3)$, the corresponding pattern is `P0P`, and the remainder is `P000000P`. The set is now:

$$\{\, \texttt{P000000P, P0P}\,\}.$$

Now, we cannot find any longer a repeating pattern whose weight is greater or equal to 2. Therefore we use the binary method for the remaining constants.

The generated code (6 operations) is given in Table 1.

Concerning the complexity, while the number of possible distances was in $O(m)$ for the previous algorithm, the number of possible triples is here in $O(m^2)$. This tends to increase the complexity, both in time and in space. However, by testing the current implementation on random values, we have found that the average time complexity of this implementation seems to be in $\Theta(m^2)$, or a close function.

4   Searching for Costs With a Computation Tree

We are interested in the search for optimal costs. We can use properties of the optimal cost function q_{opt}, coming from algebraic properties of the multiplication. Thus we will define a function f having values in $\mathbb{N}$ (nonnegative integers) and bounding above q_{opt}.

First, since we are interested in the optimal cost, we have to take into account the fact that even numbers can be generated by an optimal algorithm, due to a zero-bit shift ($c_i = 0$ in the formulation). To avoid obtaining a function partly defined on even numbers, we want to define the function f on $\mathbb{N}^*$ (positive integers), in such a way that for all $n \in \mathbb{N}^*$, we have:

---

[8]Constants are numbered starting from 0. As there is one constant at this iteration, then $i = j = 0$.

$$129x \quad \leftarrow \qquad\qquad\qquad x \quad + \quad x \ll 7 \quad (\texttt{P000000P})$$

$$5x \quad \leftarrow \qquad\qquad\qquad x \quad + \quad x \ll 2 \quad (\texttt{POP})$$

$$89x \quad \leftarrow \qquad\qquad 129x \quad - \quad 5x \ll 3 \quad (\texttt{PONONOOP})$$

$$47781511173x \quad \leftarrow \qquad\qquad 5x \quad + \quad 89x \ll 29$$

$$(\texttt{PONONOOP00000000000000000000000000POP})$$

$$47781522565x \quad \leftarrow \quad 47781511173x \quad + \quad 89x \ll 7$$

$$(\texttt{PONONOOP00000000000000PONONOOP0000POP})$$

$$47804853381x \quad \leftarrow \quad 47781522565x \quad + \quad 89x \ll 18$$

$$(\texttt{PONONOOP000PONONOOP000PONONOOP0000POP})$$

Table 1: *Code generated by the common-subpattern algorithm to compute* $47804853381x$.

$f(2n) \le f(n)$. Note that the possible additional shift is regarded as "delayed", as this has been explained in Section 2, therefore it does not generate an additional cost.

Thus the function f is the greatest function from $\mathbb{N}^*$ to $\mathbb{N}$ taking the value 0 in 1 and in 2, and satisfying the following two properties (which are also properties of the optimal cost function q_{opt}):

- Let a and b be positive integers. Without loss of generality, we can assume that $a > b$. Then $f(a \pm b) \le f(a) + f(b) + 1$. This property can be seen as a consequence of the distributivity of the addition and the subtraction over the multiplication: $(a \pm b)x = ax \pm bx$.

- Let a and b be positive integers. Then $f(ab) \le f(a) + f(b)$. This property can be seen as a consequence of the associativity of the multiplication: $(ab)x = a(bx)$.

Note: the cost function for the addition and subtraction chains problem satisfies the same properties. The only difference is that we have here: $f(2) = 0$.

To compute this function, we can start by determining the inverse images of 0 (these are the powers of 2), then successively the inverse images of $i = 1, 2, 3$, and so on, using the first property with a and b such that $f(a) + f(b) = i - 1$ and the second property with a and b such that $f(a) + f(b) = i$. The only problem is that the considered sets are infinite; in practice, we choose to limit to a fixed interval $[\![1, n]\!]$ and we find a function f_n satisfying $f_n \ge f \ge q_{\text{opt}}$.

Note that directly from the formulation of the problem, the computations can be represented as a DAG (directed acyclic graph), the cost being the number of internal nodes

(which represent shift-and-add operations). If we wish to compute the cost function for every integer (like what we are doing here) by memorizing only the values of this function, we can no longer take into account the reuse of the intermediate results, and we obtain a tree instead of a DAG. Here, we also have a tree, but a node can also represent a multiplication to take into account some forms of the reuse of results; such a node does not enter into the final cost. For instance, $861 = 21 \times 41$ can be computed from $21 = 10101_2$ and $41 = 101001_2$: 861 has a multiply node (cost 0) with parents 21 (cost 2) and 41 (cost 2), which gives a total cost of 4; 41 is used 3 times ($861 = 41 \ll 4 + 41 \ll 2 + 41$), but its cost has been counted only once in the total cost.

5   Results and Comparison of the Algorithms

We will not give any execution time of the algorithms, since contrary to Bernstein's algorithm, which has been implemented in C and carefully optimized, the algorithms based on pattern searching are still in an experimental stage: they are implemented in Perl, using high-level functions for more readability and easier code maintenance, and are not optimized at all.

Table 2 gives, for each value of q up to 9, the smallest values for which the algorithm using common subpatterns (described in Section 3.3.3) generates a code whose length is greater or equal to q. Note that the value corresponding to $q = 4$ could be computed with 3 operations by avoiding Booth's recoding and considering the pattern 101. Similarly, the value corresponding to $q = 5$ could be computed with 4 operations only by considering $1101010100\overline{1}$ (instead of $10\overline{1}010010100\overline{1}$) and the pattern 101.

q	m	smallest value	
1	2	3	11
2	4	11	1011
3	6	43	101011
4	8	213	11010101
5	11	1703	11010100111
6	14	13623	11010100110111
7	18	174903	101010101100110111
8	21	1420471	101011010110010110111

Table 2: *For each value of q up to 9, the smallest values for which the algorithm using common subpatterns generates a code whose length is greater or equal to q.*

By way of comparison, Table 3 gives, for each value of q up to 7, lower bounds on the smallest value for which one obtains a code whose length is greater or equal to q with an optimal algorithm. These results have been obtained by an exhaustive search up to a given value; it is conjectured that they are exactly the smallest values (perhaps except for $q = 7$). Results for $q = 6$ and $q = 7$ were found by Ross Donelly, who performed a search up to one billion and posted the results to the `rec.puzzles` *newsgroup*. I found the same result for $q = 6$ (using a different code).

q	m		smallest value
1	2	3	11
2	4	11	1011
3	6	43	101011
4	10	683	1010101011
5	14	14709	11100101110101
6	20	699829	10101010110110110101
7	28	171398453	1010001101110101010100110101

Table 3: *For each value of q up to 7, lower bounds on the smallest value for which one obtains a code whose length is greater or equal to q with an optimal algorithm; in fact, it is conjectured that these are exactly the smallest values (perhaps except for $q = 7$).*

The highest difference in the code quality between Bernstein's algorithm and our algorithm for numbers between 1 and 2^{20} is obtained for $n = 543413$; our algorithm generates 4 operations:

$$
\begin{aligned}
1. \quad & 255x & \leftarrow & \quad x \ll 8 & - & \quad x \\
2. \quad & 3825x & \leftarrow & \quad 255x \ll 4 & - & \quad 255x \\
3. \quad & 19125x & \leftarrow & \quad 3825x \ll 2 & + & \quad 3825x \\
4. \quad & 543413x & \leftarrow & \quad x \ll 19 & + & \quad 19125x
\end{aligned}
$$

whereas Bernstein's algorithm generates 8 operations:

$$
\begin{aligned}
1. \quad & 9x & \leftarrow & \quad x \ll 3 & + & \quad x \\
2. \quad & 71x & \leftarrow & \quad 9x \ll 3 & - & \quad x \\
3. \quad & 283x & \leftarrow & \quad 71x \ll 2 & - & \quad x \\
4. \quad & 1415x & \leftarrow & \quad 283x \ll 2 & + & \quad 283x \\
5. \quad & 11321x & \leftarrow & \quad 1415x \ll 3 & + & \quad x \\
6. \quad & 33963x & \leftarrow & \quad 11321x \ll 2 & - & \quad 11321x \\
7. \quad & 135853x & \leftarrow & \quad 33963x \ll 2 & + & \quad x \\
8. \quad & 543413x & \leftarrow & \quad 135853x \ll 2 & + & \quad x.
\end{aligned}
$$

However, Bernstein's algorithm is also better than our algorithm on some constants; the highest difference can be up to 3 operations for numbers between 1 and 2^{20}.

Table 4 gives the average number of operations for an m-bit constant ($2 \le m \le 27$) with

- Bernstein's algorithm,

- our algorithm using common subpatterns (CSP),

- the same algorithm but considering all the possible transformations PON $\leftrightarrow$ OPP and NOP $\leftrightarrow$ ONN (CSP+),

- a search for the costs using a computation tree (see Section 4),

- an exhaustive search (on all possible DAG's whose nodes represent additions or subtractions), by considering values up to one billion; as we performed a bounded search, the given results are only (good) approximations to the optimal values.

Note that our algorithm becomes better than Bernstein's algorithm in average from $m = 12$ (which is more important, since we can use a table or a specific algorithm for small constants). The other two algorithms cannot be used as they are in the general case, but we can deduce the following points from the results:

- it is a priori interesting to consider the transformations PON $\leftrightarrow$ OPP and NOP $\leftrightarrow$ ONN (refer to the discussion in Section 3.3.2);

- the search using a computation tree, which is based on an exhaustive search without trying to reuse intermediate results, seems to be better than the algorithms based on the search for common subpatterns, which, on the contrary, try to reuse intermediate results.

For much larger values of m, there are too many numbers to test; therefore we can only perform tests on random values. Moreover, Bernstein's algorithm would take too much time. So, we decided to test only the algorithms based on pattern searching: the one described in Section 3.3.1 and the one described in Section 3.3.3. The results are given in Table 5.

It seems that in both above cases, we have $q_{av} = O(m/\log m)$, but the first values of q_{av}, though accurate, are not very significant to have an idea about the asymptotic behavior of q_{av}, the next values are not very accurate and finally, we have few values in total. We need to carry on with the computation of q_{av} to have a better idea of its asymptotic behavior (unless we can find a direct proof).

6   Conclusion

We described a new algorithm allowing to perform multiplications by integer constants. This algorithm can also be used to multiply a single number by different constants at the same time. But many questions have not been studied yet and remain open. In particular:

m	Bernstein		CSP		CSP+		Tree		DAG's
2	1	(0.0 %)	1	(0.0 %)	1	(0.0 %)	1	(0.0 %)	1
3	1	(0.0 %)	1	(0.0 %)	1	(0.0 %)	1	(0.0 %)	1
4	1.5	(0.0 %)	1.5	(0.0 %)	1.5	(0.0 %)	1.5	(0.0 %)	1.5

Table 4: *Average number of operations for a m-bit constant with Bernstein's algorithm, with our algorithm using common subpatterns (CSP), with the same algorithm but considering all the possible transformations* PON ↔ OPP *and* NOP ↔ ONN *(CSP+), with a search for the costs using a computation tree (note: these results are not proved, for we have taken the function f_n with $n = 2^{29}$; however, there should not be any difference, with the given precision), and with an exhaustive search up to one billion (conjectured optimal). The percentages represent the loss relative to the exhaustive search costs. Note: these means were computed by using* all *the m-bit constants.*

m	$q_{\text{algo 1}}$	$q_{\text{algo 2}}$	saving
8	2.6	2.6	0.0%
16	4.4	4.4	0.0%
32	8.0	7.6	5.0%
64	14.5	13.4	7.6%
128	26.3	23.7	9.9%
256	47.6	42.2	11.3%
512	86.5	75.5	12.7%
1024	157.7	135.4	14.1%
2048	290.0	243.3	16.1%
4096	536.9	440.3	18.0%
8192	1001.9	802.8	19.9%

Table 5: *Average number of operations for a m-bit constant with both algorithms based on pattern searching (described in Sections 3.3.1 and 3.3.3). These numbers were computed by considering random m-bit constants, therefore they are approximate numbers. The saving is the value of* $1 - q_{\text{algo 2}}/q_{\text{algo 1}}$.

- Is this problem NP-complete? What can be said about the asymptotic behavior of the optimal quality (in average, in the worst case)? Same question concerning the various heuristics. What complexity (in average, in the worst case, in time, in space) can be obtained?

- How can the heuristics be improved? Is it interesting to use other elementary operations, like right shifts or the *logical or*?

- How much memory does the generated code take, that is, how many temporary results need to be saved? How can temporary results be avoided?

- Other ways can be explored to find new heuristics. For instance, can we find interesting algorithms by writing the constant in a properly chosen numeration system?

- The following relation on the positive integers can be defined: $m \rightsquigarrow n$ if the computation of n can use m as a temporary result. The best would be to apply this definition to the set of the optimal computations[9]. Note that $n \rightsquigarrow n$ and that insofar as the cost of an integer is well-defined (it is the quality of the generated code), one has $m \rightsquigarrow n \Rightarrow q(m) < q(n)$; as a consequence, the relation is antisymmetric. But it is not

---

[9]It can also be applied to the codes generated by a particular heuristic, but this would not necessarily be interesting.

necessarily transitive. The study of this relation, for instance knowing the numbers that have many "successors", could allow to find other heuristics.

7   Thanks
