Abstract: Recent hierarchical global illumination algorithms permit the generation of images with a high degree of realism. Nonetheless, appropriate refinement of light transfers, high quality meshing and accurate visibility calculation can be challenging tasks. This is particularly true for scenes containing multiple light sources and scenes lit mainly by indirect light. We present solutions to these problems by extending a global visibility data structure, the Visibility Skeleton. This extension allows us to calculate exact point-to-polygon form-factors at vertices created by subdivision. The structure also provides visibility information for all light interactions, allowing intelligent refinement strategies. High-quality meshing is effected based on a perceptually-based ranking strategy which results in appropriate insertions of discontinuity curves into the meshes representing illumination. We introduce a hierarchy of triangulations which allows the generation of a hierarchical radiosity solution using accurate visibility and meshing. Results of our implementation show that our new algorithm produces high quality view-independent lighting solutions for direct illumination, for scenes with multiple lights and also scenes lit mainly by indirect illumination.

Key-words: Global Illumination, Global Visibility, Form Factor Calculation, Discontinuity Meshing, Hierarchical Triangulation

Radiosité hiérarchique rapide et précise avec visibilité globale

Résumé : Les algorithmes hiérarchiques récents d'éclairage global permettent de produire des images d'un très grand réalisme. Cependant, le raffinement pertinent des transferts lumineux, la construction d'un maillage de qualité et la réalisation de calculs précis de visibilité posent des problèmes difficiles. Cela est particulièrement vrai pour les scènes éclairées par de multiples sources de lumière ou pour les scènes illuminées principalement par de l'éclairage indirect. Nous présentons des solutions à ces problèmes, en étendant une structure de données de visibilité globale, le squelette de visibilité. Cette extension nous permet d'effectuer des calculs exacts de facteur de forme point-polygone aux sommets issus de la subdivision des polygones initiaux. Cette structure permet également d'obtenir des informations de visibilité pour toutes les interactions lumineuses, ce qui autorise des stratégies efficaces de raffinement. Des critères d'estimation perceptuelle guident la construction d'un maillage de qualité représentant l'éclairage, incluant les courbes de discontinuité pertinentes. Une hiérarchie de triangulations permet de calculer une solution de radiosité hiérarchique utilisant une visibilité et un maillage précis et efficaces. Le nouvel algorithme produit des simulations d'éclairage indépendantes du point de vue de très haute qualité pour des scènes avec éclairage direct, pour des scènes présentant de nombreuses sources de lumière ainsi que pour des scènes avec éclairage indirect.

Mots-clé : Illumination globale, visibilité globale, calcul de facteurs de forme, maillage de discontinuité, triangulation hiérarchique

1 Introduction and Previous Work

Recent advances in global illumination, such as hierarchical radiosity [HSA91] and its combination with discontinuity meshing [LTG93] have resulted in high quality lighting simulations. These lighting simulations are *view independent* and are suitable for walkthroughs. The quality of the resulting illumination is important everywhere in the scene, since the user can, for example, approach a shadow of an object and see its details.

Despite the high quality of existing techniques, certain aspects of these algorithms are still suboptimal. In particular, deciding when a light-transfer is *refined* appropriately, and thus computed with higher precision is a hard decision; current algorithms ([HSA91, LSG94, GH96] etc.) include methods based on error bounds which in many cases prove insufficient. Creating a *mesh* to represent lighting variations accurately (notably for shadows) is hard; discontinuity meshing approaches [LTG93, DS96] have proposed some solutions for these issues which are however often limited in their applicability. Recent approaches (e.g., [CSSD96]) avoid this problem by performing a view-dependent, ray-casting “final gather”; view-independence and the capacity for interactive display and walkthroughs are thus sacrificed. Accurate *visibility* calculation is also fundamentally hard, since we have to consider the potential interaction between all polygons in the scene for global illumination.

The above three problems, *visibility*, *refinement* and *meshing* are accentuated in certain lighting configurations: scenes lit by multiple sources and scenes lit mainly by indirect illumination. In this paper we present a new algorithm which addresses the three shortcomings. We show how our approach achieves a significant improvement for the aforementioned difficult cases. For all three problems, previous approaches lack information on accurate *global visibility* relationships in the scene. This information is provided by the *Visibility Skeleton* [DDP97]. To achieve our goal, we first extend the Skeleton to provide visibility information at vertices resulting from subdivision of the original input surfaces. The extended Skeleton allows the fast computation of exact point-to-polygon form-factors for any point-polygon pair in the scene. In addition, all visibility information (blockers and all discontinuity surfaces) is available for any polygon-polygon pair.

This global visibility information allows us to develop an intelligent refinement strategy, since we have knowledge of visibility information for *all* light transfers from the outset. We can *rank* discontinuity surfaces between any two hierarchical elements (polygons or patches resulting from their subdivision), using perceptually-based techniques [GH97]; thus only discontinuities which are visually important are considered. An appropriate mesh is created using these discontinuities; illumination is represented very accurately resulting in high-quality, view-independent meshes. To achieve this in the context of a hierarchical radiosity algorithm, we have introduced a hierarchy of triangulations data structure. Radiosity is gathered and stored at vertices, since the extended Skeleton provides us with the exact vertex-to-polygon form-factor. An appropriate multi-resolution push-pull procedure is introduced. The high-quality mesh, the exact form-factor calculation and the hierarchical triangulation result in lighting simulation with accurate visibility.

Our approach is particularly well-suited for the case of multiple sources since the discontinuity ranking operates simultaneously on *all* light sources arriving at a receiver. Indirect illumination is also handled very well, since visibility information, and thus the refinement and meshing strategies as well as the form-factor computation apply equally well to all interactions, i.e., both direct (from the sources) and indirect (reflected light). Examples of these two cases are shown in Fig. 1. In Fig. 1(a) we see a scene lit by 10 separate light sources, where the multiple shadows are visible but the mesh complexity is reasonable (see Table 2, in Section 7.2). In Fig. 1(b) we see a room lit mainly by indirect lighting; notice the high quality shadows created entirely by indirect light (e.g., on the far wall from the books and lamp).

1.1 Previous Work

The new algorithm we present here is in a certain sense an extension of hierarchical radiosity, using visibility structures, advanced meshing techniques and perceptually-based subdivision. We briefly review hierarchical radiosity methods, accurate visibility techniques and related visibility-based refinement for lighting algorithms and finally perceptually-based refinement for illumination.

Figure 1: Images computed using our new hierarchical radiosity algorithm based on the extended Visibility Skeleton and hierarchical triangulations. (a) A scene with multiple sources. The skeleton construction took 2min 23s and the lighting simulation 8min. (b) a scene mainly lit by indirect light. The skeleton construction took 4min 12s and the lighting simulation 6min 58s. Note the indirect shadows cast by the books on the back wall.

Hierarchical radiosity

The hierarchical radiosity algorithm [HSA91] allows efficient calculation of global illumination. Lighting calculations are limited to a user-specified level of accuracy, by means of hierarchically subdividing the polygons in the scene into a quadtree, and creating light-transfer “links” at the appropriate levels of the hierarchy. In the original hierarchical radiosity solution [HSA91], radiosity is considered constant over each quadtree element. The rectangular nature of the quadtree, and the constant reconstruction result in the need for very fine subdivision for high quality image generation (high quality shadows etc.).

Higher-order (non-constant) methods have also been introduced, notably in the context of wavelet-based solutions [GSCH93]. The wavelet-based radiosity solutions presented to date typically operate on discontinuous bases, resulting in visible discontinuities if the solution is displayed directly (e.g., [CSSD96]). Zatz [Zat93] used a Galerkin-type method and shadow masks to improve the quality of the shadows generated. To avoid the problem of discontinuous representations the “final gather” step was introduced by [Rei92] and used for wavelet solutions (e.g., [CSSD96]). A final gather step consists of creating a ray-cast image, by querying the object-space visibility and lighting information to calculate illumination at each pixel. This approach allows the generation of high quality images from a coarse lighting simulation, at an additional (frequently high) cost. The solution thus becomes view-dependent, and interactive display and walkthrough capability are lost.

Accurate Visibility and Image Quality

The accurate calculation of visibility in a lighting simulation is essential: both the numerical quality of the simulation and the visual quality of the resulting image depend on it. The exact computation of visibility between two patches in a scene or between a patch and a point requires the treatment of *visual events*. Visual events are caused at boundaries in a scene where the visibility of one object changes with respect to a point of view. Such events occur at boundaries generated by the interaction between vertices and edges of the environment (see Section 2). In the case of the view of a light source, these boundaries correspond to the limits of umbra and penumbra. By choosing certain of these boundaries and using them to guide the (irregular) mesh structure, *dis-*

continuity meshing lighting algorithms have been introduced resulting in more visually accurate images (e.g., [Hec92, LTG92]).

In the vision literature, visual events have been extensively studied [PD90, GCS91]. The *aspect graph* structure completely encodes all visibility events in a scene. The determination of the visible part of an area light source in computer graphics is exactly the calculation of the aspect of the light at a given point. Algorithms performing this operation by building the complete discontinuity mesh and the *backprojection* data structure (encoding the source aspect) have been presented (e.g., [Tel92, DF94, SG94]). The full discontinuity mesh and backprojection allows the computation of the exact point-to-area form-factor with respect to an area light source. Nonetheless, these methods suffer from numerical problems due to the required intersections between the discontinuity surfaces and the scene polygons, complicated data-structures to represent the highly irregular meshes and excessive computational requirements. The Visibility Complex [DDP96] and its simplification, the Visibility Skeleton [DDP97], present complete, *global* visibility information between any pair of polygons. We have chosen to use the Visibility Skeleton because of its flexibility, relative robustness (compared to discontinuity meshing) and ease-of-use. A review of necessary machinery from the Skeleton used here is presented in Section 2.

Visibility-Based Refinement Strategies for Radiosity

In the Hierarchical Radiosity algorithm, mesh subdivision is effected through link refinement. The original algorithm used a *BF* criterion (radiosity times form-factor) modulated by a visibility factor *V* for partially occluded links. The resulting meshes are often too fine in unoccluded regions, and do not always represent fine shadow details well.

Refinement strategies based on error bounds [LSG94, GH96] have improved the quality of the meshes and the simulation compared to the *BFV* criterion. Conservative visibility determination in architectural scenes [TH93], accurately characterises links as *visible*, *invisible* or *partially visible*. This triage guides subdivision, allowing finer subdivision in partially illuminated regions.

Discontinuity meshing clearly improves the visual quality of images generated by lighting simulation [LTG92, Hec92, DF94], since the mesh used to represent illumination follows the actual shadow boundaries, instead of finely subdividing a quadtree which attempts to approximate the boundary. One problem is the extremely large number of discontinuities. Tampieri [Tam93] attempted to limit the number of discontinuity lines inserted, by sampling the illumination along the discontinuities and only inserting those with radiosity values differing more than a predefined threshold. In the context of progressive refinement radiosity, Stuerzlinger [Stu94], only inserted discontinuities at a second level of a regular quadrilateral adaptive subdivision, once a ray-casting step has classified the region as important. The only discontinuities inserted were those due to blocker identified by the ray caster.

Several methods combining discontinuity meshing with hierarchical radiosity have been presented [LTG93, DS96, HT96, BP95]. Hardt and Teller [HT96] present an approach in which potential discontinuities from all surfaces are considered, without actually intersecting them with the blockers. Potential discontinuities are ranked, and those deemed most important are inserted and the lowest level of the quadtree. In [DS96] the backprojection information is used in the complete discontinuity mesh creating a large number of small triangles. Exact form-factors of the primary source are then computed at the vertices of these triangles. The triangles are then clustered into a hierarchy. Standard [HSA91] constant-element hierarchical radiosity follows. The previously cited problems of discontinuity meshing, the expensive clustering step and the fact that the inner nodes of the hierarchy often overlap, limit the applicability of this approach to small models. The only other hierarchical radiosity method with gathering at vertices is that of Martin et al. [MPT97], which requires a radiosity values at each vertex, and a complex push procedure.

The algorithm of Lischinski et al. [LTG93] is much more complete and relevant to our work. The basis of this approach is to separate the light simulation and rendering steps. This idea is similar in spirit to the use of a “final gather” step. Lischinski et al. first compute a “global pass” by creating 2D BSP trees on scene polygons subdivided by choosing important discontinuities exclusively due to the primary sources. The 2D

BSP tree often incurs long splits and consequently long or thin triangles, which are inappropriate for high quality lighting simulation. The second, view independent, “local pass” recomputes illumination at the vertices of a triangulated subdivision of the leaf elements of the BSP tree. To achieve high quality images, the cost of triangulation and shading (light recomputation at vertices using “method D” [LTG93]), is higher than that of the actual lighting simulation (if we ignore the initial linking step).

Perceptually Based Refinement

Recently, perceptually-based error metrics have been used to reduce the number of elements required to accurately represent illumination (e.g., [GH97, HWP97]). Tone-reproduction approaches [TR93, War94] are used to map calculated radiosity values to display values which convey the perceptual effect closer to that perceived by a real world viewer. Since display devices have limited dynamic range compared to real world luminance values, the choice of this mapping is very important. The tone reproduction mappings of [TR93, War94] depend on two parameters: a world adaptation level which corresponds loosely to the brightness level at which a hypothetical observer’s eye has adapted, and a display adaptation level which corresponds to the brightness displayed on the screen. Choice of these parameters affects what will be displayed, and, more importantly, which differences in radiosities will actually be perceptible in the final image. Most notably, one can define a “just noticeable difference” using this mapping. In the context of lighting, a just noticeable difference would correspond to the smallest difference in radiosity values, which once transformed via tone reproduction, will be visible to the viewer of the display. Display adaptation is typically a fixed value (e.g., half the maximum display luminance [War94]), while the world adaptation level can be chosen in a number of different ways. Using static adaptation [GH97], one uses an average which is independent of where the observer is looking, while dynamic adaptation (which is closer to reality) changes depending on where the observer is looking. Gibson and Hubbard [GH97] use tone reproduction to guide subdivision in a progressive refinement radiosity approach, thus allowing a subdivision only if the result will be “just noticeable”.

Hedley et al. [HWP97], in a similar spirit, use a tone mapping operator to determine whether a discontinuity should be inserted into a lighting simulation mesh. This is performed by sampling across the discontinuity (in a manner similar to that of Tampieri [Tam93]), but also orthogonally across the discontinuities. This results in an important reduction of discontinuities without loss of visual quality.

1.2 Paper Overview

Previous algorithms surveyed above provide view-independent lighting simulations which are acceptable for many situations. In particular, quadtree based hierarchical radiosity provides fast solutions of moderate quality, even for scenes mainly lit indirectly. Nonetheless, in walkthroughs the observer often approaches regions of shadow, and in these cases the lack of shadow precision is objectionable. Previous approaches based on discontinuity meshing alleviate this problem for direct lighting, but rapidly become impractical for scenes with many lights, or for which indirect lighting is dominant.

The new algorithm presented here allows the generation of accurate shadows for such scenes. To achieve this goal we extend the Visibility Skeleton to support view calculation at vertices resulting from subdivision, and to use a link-based storage mechanism which is more adapted to a hierarchical radiosity approach. This extended structure is presented in Section 2. The resulting structure allows us to select and insert discontinuity lines for all light transfers, and to calculate exact point-to-area form-factors rapidly using the visibility information provided. These choices required us to develop a new hierarchical radiosity algorithm, with gathering at vertices, based on embedded *hierarchical triangulations* allowing the mesh to follow discontinuity lines. The details of this structure, and the novel push-pull algorithm are presented in Section 3. In Section 4 we present the new hierarchical radiosity algorithm using accurate global visibility and we present the new point-polygon and polygon-polygon link data structures. In Section 5 we present the corresponding refinement processes and the visibility updates required for their use. In Section 6 polygon subdivision and the perceptually-based refinement criterion are described. We then present results of our implementation, as well as a discussion of relative limitations and advantages of our approach, and we conclude.

2 The Visibility Skeleton

The Visibility Skeleton [DDP97] is a graph in line space encoding *global* visibility based on visual events.

Figure 2: (a) An *EV* line swath, (b) The *VEE* node is adjacent to two line swaths (c) The graph structure induced (Figure taken from Durand et al.[DDP97])

The nodes of the graph represent *extremal stabbing lines* [Tel92], which are lines passing through four edges of the scene. Examples of such lines are vertex-vertex (*VV*) lines passing through two vertices, vertex-edge-edge (*VEE*) lines passing through two edges and a vertex or 4-edge (*E4*) lines passing through four edges. The arcs of the graph are *line swaths*, which are surfaces swept by stabbing lines when one constraint is relaxed. Such swaths are caused by the interaction of an edge and a vertex (*EV* swaths) or three edges (*EEE*) swaths. The nodes of the graph are adjacent to a certain number of arcs (swaths), which are defined in a catalogue for each type of node [DDP97].

A visibility event is the locus of the topological changes in visibility. An example is shown in Fig. 2(a) (taken from [DDP97]), when the viewpoint moves from left to right, vertex v as seen from the observer will no longer lie on the floor, and will now be on the polygon adjacent to edge e .

Fig. 2(b) shows the adjacencies of a *VEE* extremal stabbing line and two *EV* critical line swaths. The graph-structure induced, consisting of a node and the two arcs, is shown in Fig. 2(c).

Efficient access to the skeleton information is provided by means of an n^2 array (where n is the number of objects in the scene) indexed by the polygons at the extremities of the swaths. The endpoints of the arcs, the nodes (extremal stabbing lines) are determined with a ray-casting operation. This method is simpler than traditional discontinuity meshing algorithms since we perform geometric calculations only on single lines (the extremal stabbing lines) instead of computing complicated swath-polygons intersections (e.g., [DF94]). The resulting memory requirements are however significant.

The construction of the Skeleton proceeds as a set of nested loops over the edges and vertices of the scene to determine the nodes. First simple cases (e.g., *VV* and face nodes) are found, and subsequent loops over the edges allow the identification of *VEE* and *E4* nodes. For each node type, the adjacent swaths are defined in a corresponding catalogue, and are appropriately created. Adjacencies between nodes and swaths are correctly updated using the array to find potentially neighboring graph elements.

2.1 Extensions to the Visibility Skeleton

Memory requirements

The storage of the arcs of the Skeleton in a two dimensional array incurs an $O(n^2)$ cost in memory. In the scenes presented in [DDP97] half of the memory was used for the array, in which more than 95% of the cells

were empty! It is even more problematic when the scene is highly occluded such as in the case of a building where each room sees a only fixed number of other rooms: the number of arcs is only $O(n)$. Moreover, for our lighting simulation, we will need to subdivide the initial polygons into sub-patches and incrementally compute visibility information between some pairs of sub-patches, but not all.

For these reasons we now store the set of critical line swaths between two polygons on the polygons themselves. Each polygon P stores a balanced binary tree; each node of this tree contains the set S of arcs between P and another polygon Q . This set is itself organized in a search tree. Each set S of arcs is referenced twice, once on P and once on Q . In the same manner, each vertex V has a search tree containing the sets of arcs between V and a polygon Q (which represents the view of Q from V). These sets of arcs are closely related to the notion of *links* in hierarchical radiosity as we will see in section 4.2.

For the scenes presented [DDP97], this approach results in an average memory saving of about 30%. Moreover, we have ran our modified version of the visibility skeleton on a set of scenes consisting of a room replicated 2, 4, and 8 times, showing roughly linear memory growth. Using a binary tree instead of an array incurs an additional $O(\log n)$ time access cost, but this was not noticeable in our tests.

Visibility Information at Vertices from Subdivision

To permit the subdivision of surfaces required to represent visual detail (shadows etc.) on scene polygons, visibility skeleton information must be calculated on the triangles created by the subdivision and the corresponding interior vertices. The process is presented in detail in Section 5.

Since the visibility information is now stored on polygons and vertices (instead of a 2D array), the generalization to subdivided polygons is straightforward. On each sub-patch or sub-vertex, we store the visibility information only for the patches it interacts with.

2.2 Treating Degenerate Configurations

Computational geometry often makes the assumption that the scene considered are in a “general configuration”. Unfortunately, computer graphics scenes are very often highly degenerate: many points are aligned, segments or faces are parallel or coplanar and objects touch each other.

This results in degenerate visibility events; e.g, VVV extremal stabbing lines passing through three aligned vertices, or $E5$ stabbing lines going through five edges.

To deal with these problems, we first have to identify their occurrence. When a potential extremal stabbing line is tested for occlusion, we also check for grazing objects. This required a simple modification to the point-in-polygon test, thus detecting the intersection with a silhouette edge or vertex.

We also have to deal with the aforementioned degenerate extremal stabbing lines. A first possibility is to explicitly create a catalogue of all these degeneracies. This approach however quickly makes the implementation intractable because of the large number of different cases. We have chosen to always consider the simplest configuration, that is the one in which we have the smallest number of visual events. For example, if four edges E_1 , E_2 , E_3 and E_4 are parallel in that order, we consider that E_2 occludes E_1 and then E_3 occludes E_2 etc. The configurations to be treated are thus simpler and correspond to the standard Skeleton catalogue of events. The problems of numerical precision are treated using a consistent ϵ threshold for equality and zero tests.

3 Irregular Hierarchical Triangulations for Illumination

In previous work (e.g., [Hec92, LTG92]) it has been shown that the creation of a mesh well adapted to the discontinuities in illumination results in images of high visual quality. Incorporating such irregular meshes into a hierarchical radiosity algorithm presents an important challenge. As mentioned in Section 1.1, most previous algorithms [LTG93, DS96] addressing this issue have restricted the treatment of discontinuities to those due to direct (primary) illumination.

The core of the problem is that two conflicting goals are being addressed: that of a simple regular hierarchy, permitting straightforward manipulations and neighbor finding and that of an essentially irregular mesh, required to represent the discontinuity information. The first goal is typically achieved using a traditional quadtree structure [HSA91] and the second typically by a BSP-type approach [LTG93].

In previous approaches, discontinuity information and accurate visibility were incorporated into constant-element hierarchical radiosity algorithms. In the case of the Skeleton, this would be wasteful, since we have all the necessary information to compute *exact* form-factor from any polygon in the scene to any vertex (see Section 5 to see how this is also true for vertices resulting from subdivision). Gathering to vertices introduces one important complication: contrary to elements whose level in the hierarchy is clearly defined, vertices are shared between hierarchy levels.

As a solution to the above issues, we introduce hierarchical triangulations for hierarchical radiosity. Our approach has two major advantages over previous hierarchical radiosity methods: (i) it adapts well to completely irregular meshes and this in a local fashion (triangulations contained in triangulations), avoiding the artifacts produced by splitting edges of a 2D BSP tree and (ii) it allows gathering to vertices by a “lazy wavelets”-type (or sub-sampling) construction, which preserves a linear approximation to radiosity during the gather and the push process of the solution.

Figure 3: Hierarchical Triangulation Construction. Notice how the triangles are overall well shaped but also well adapted to local detail. (a) Scene geometry: the leftmost polygon is illuminated by the area source on the right pointing leftwards. (b) First level of subdivision for the leftmost polygon (green). (c) Second level (blue). (d) third level (red).

3.1 Hierarchical Triangulation Construction

Our hierarchical triangulation construction has been inspired by that of de Floriani and Puppo [DP95]. As in their work we start with an initial triangulation, which is a constrained Delaunay triangulation (CDT). The CDT allows the insertion of constrained edges into the triangulation, which are not modified to satisfy the Delaunay property and thus remain “as is”. Each triangle of the initial triangulation can be subdivided into a sub-triangulation, and so on recursively. At each level, a CDT is maintained.

An example of such a construction is shown in Figure 3, clearly showing the first advantage mentioned above. As we can see, the triangulation maintains well-shaped triangles everywhere in the plane, while providing fine details in the regions where this is necessary.

Our hierarchical triangulation is “matching”, in the sense that edges split across two levels of a triangulation are done so at the same point on the edge. At the end of each subdivision step an “anchoring” operation is performed by adding the missing points in the neighboring triangles, thus resulting in a conforming triangulation across levels required for push.

Figure 4: The “matching” constraint for the Hierarchical Triangulation. The sequence shows subsequent insertions. The dashed lines show the insertions performed to enforce the “matching” constraint.

As mentioned above, vertices are shared between different levels of the triangulation. The initial level of a triangulation is an *HPolygon*, which contains an *HTriangulation* child once subdivided. The construction is shown in Fig. 5.

To transmit neighborhood information between levels (for the matching operation), we use a special *HEdge* structure. An *HEdge* is shared between hierarchy levels by all edges which correspond to the same segment. It contains pointers to sub *HEdge*’s when it is subdivided. To perform a matching operation we determine whether the edge on which we insert a point p has already been split. We then add the new points corresponding to the previously split vertices, and split the *HEdge* at the point p . The neighboring triangle can thus identify the newly inserted sub-*HEdge*’s from the shared *HEdge*. For example, in Figure 4, after the subdivision of the lower left triangle in Fig. 4(a), the *HEdge* shared between the two triangles notifies the upper right triangle that the edge has been split, and facilitates the matching operation as shown in Fig. 4(b).

```

class HPolygon { // Initial level is an HPolygon
    HTriangulation *child // Created when the HPolygon is subdivided
    HVertex *vertices
}

class HTriangulation {
    QuadMesh *mesh // Constrained Delaunay Triangulation
}

```

Figure 5: The hierarchical triangulation data structure

3.2 Linear Reconstruction of Illumination using Hierarchical Triangles

The second advantage, that of linear reconstruction of illumination across irregular meshes, requires the use of a “lazy-wavelet” or “sub-sampling” type construction.

3.2.1 Push-pull

As mentioned above, in our hierarchical triangulation representation of radiosity, vertices will be shared between hierarchy levels. As a consequence, traditional push-pull procedures cannot be directly applied. A simple and compact alternative is the use of a “lazy-wavelet” type construction.

Figure 6: (a) The initial coarse representation of the function (b) Additional value B_2 (c) The ΔB value is stored instead of the B_2 permitting consistent linear reconstruction

For clarity we explain the principle in 1D. Consider the 1D function shown in Fig. 6(a), defined on a line at two points with values B_0 and B_1 . Consider this to be a coarse approximation of the function; later, we decide to calculate the value B_2 of the function in the interior point shown in Fig. 6(b). Instead of maintaining the value B_2 , we simply store the *difference* ΔB , shown in Fig. 6(c). When performing the “push” operation on this hierarchy, to extract the value of B_2 , all that is required is to compute:

$$B_2 = \alpha B_1 + (1 - \alpha) B_0 + \Delta B. \quad (1)$$

This construction applies directly to the 2D case, by using barycentric coordinates (or bilinear for quadrilaterals) in the place of the coefficient α . We thus can simply perform a push operation on a hierarchical triangulation with gathering at the vertices.

The pull computation is much simpler, since we pull values to the triangles. At each triangle leaf, the value given is simply the average of values at the vertices (after the pull). An intermediate node receives as a value the area-weighted average of its children triangles, as in standard hierarchical radiosity.

The advantages of this approach are that we can now create a consistent multi-resolution representation of radiosity over the hierarchical triangulation, while gathering at vertices. In addition, the push operation maintains a linear reconstruction of the radiosity function down to the leaf level.

4 Visibility-Driven Hierarchical Radiosity: Algorithm and Data Structures

The hierarchical triangulation structure is one of the tools required to effect visibility-driven hierarchical radiosity. In particular, we can efficiently represent the irregular lighting discontinuities in a hierarchical structure. In addition, the information contained in the extended Visibility Skeleton provides *exact* and *global* visibility information. As a consequence, we can compute exact (analytical) area-to-point form factors for any light transfer, direct (primary) or indirect. The information contained in the Skeleton arcs (i.e. the visibility events affecting any light transfer) also allows the development of intelligent refinement criteria, again for any exchange of light.

In what follows we present our new algorithm which uses the extended Skeleton and the hierarchical triangulations for efficient refinement and accurate light transfer.

4.1 Algorithm Outline

Our new algorithm is outlined in Fig. 7. It begins with the creation of the Visibility Skeleton for the given scene, using the improved link-based approach (Section 2.1). After this step, we have all the information available to calculate form-factors from each polygon to each (initial model) vertex in the scene. In addition, polygon-polygon visibility relationships are available directly from the skeleton, thus obviating the need for initial linking (i.e. only necessary links are created). After computing the form-factors of the initial polygons to the initial vertices, a “gather” step is performed to the vertices, and a “push-pull” process is performed. The gather/push-pull step is repeated several times (procedure *computeCoarseLighting()*) resulting in a first, coarse distribution of light in the scene. Note that even at this very initial phase, the form-factors at the vertices of the scene are exact. To bootstrap subdivision, we first insert the maxima of the light source illumination functions into large receiver polygons (procedure *insertMaxima()*, see also Section 6.2).

```
visibilityDrivenHR
{

Figure 7: Visibility Driven Hierarchical Radiosity

Once the system has been initialized in this manner, we begin discontinuity based subdivision (*subdividePolygons()*) and link refinement (*refineLinks()*). Using the global visibility information, we are capable of subdividing surfaces by following “important” discontinuities. After the completion of each subdivision/refinement step, a gather/push-pull operation is performed, resulting in a consistent multi-resolution representation of light in the scene.

In the following discussion we use the terms “source” and “receiver” for clarity. A source is any polygon in the scene which emits or reflects light. For secondary or tertiary illumination, for example, “sources” will be polygons other than the primary light sources (e.g., the walls, ceiling or floor of a room).

In the rest of this section, we present the link data structures and discuss issues related to form-factor calculation and multi-resolution link representation. In Section 5 we describe the refinement process for links, and the details of visibility updates; in Section 6 we present the polygon subdivision strategy and the perceptually-based refinement criterion used to effectively perform the subdivision.

4.2 Link Data Structures and Form-Factors

The central data structures used for our lighting solution are the links used to perform subdivision and perform light transfers. In contrast to previous hierarchical radiosity methods, two distinct link types are defined: point-polygon links which are used to gather illumination at vertices, and polygon-polygon links, which are used to determine refinement decisions and to maintain visibility information while subdividing.

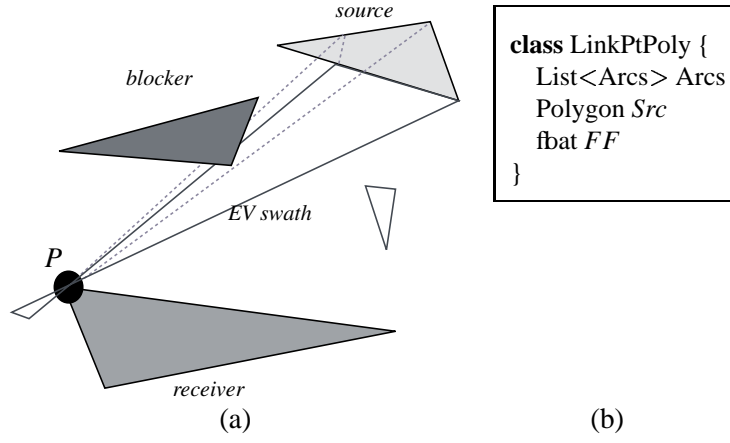

Figure 8: (a) A point-polygon link used to gather illumination at vertex P . Note that all the arcs of the skeleton between P and the triangle *source* are stored with the link, e.g., the *EV swath* shown. (b) The corresponding data structure.

4.2.1 Point-Polygon Links

As mentioned above, the skeleton provides all the information required to calculate the exact area-to-point form-factor from any polygon in the scene to any vertex. By updating the view information as shall be discussed below (Section 5.3), we extend this capacity to new vertices created by subdivision.

There are numerous advantages to calculating illumination at vertices. This approach was first used by Wallace [WEH89] in the context of progressive refinement radiosity. For hierarchical radiosity, the fact that vertices can be shared between different levels renders gathering at vertices more complicated.

A point-polygon link and the corresponding data structure are shown in Fig. 8. The point-polygon links are stored at each vertex of the hierarchical triangulations. A point-polygon link stores the form-factor calculated, as well as the arcs of the visibility skeleton (visibility events of the view) between the point and the polygon. An example is shown in Fig. 8, where the *EV swath* is stored with the link between point P and the source triangle.

Figure 9: Geometry for the calculation of form factor

The point-area form factor is computed analytically using the formula in e.g. [BRW89]. Consider Fig. 9.

$$F_{P,source} = \frac{1}{2\pi} \vec{N} \bullet \sum \gamma_i \frac{\vec{R}_i \times \vec{R}_{i+1}}{\|\vec{R}_i \times \vec{R}_{i+1}\|}$$

The sum is evaluated using the arcs of the skeleton stored in the point-polygon link. \vec{R}_i and \vec{R}_{i+1} correspond to the two nodes (extremal stabbing lines) of the arc.

Fig 10 shows an example of form-factor computation with the Visibility Skeleton; the computation is exact. For comparison, the average (relative) error is given using ray-casting and a jittered grid sampling on the source. Note that 36 rays are needed to have a mean error of 10%. In Section 7.2 we will show the effect of this accuracy on the image quality.

	Skeleton	4 rays	16 rays	36 rays	64 rays	100 rays
time	0.07ms	0.5ms	1.7ms	3.8ms	6.7ms	10.4ms
error	0	50%	20 %	9.6%	7.6%	4.6 %

Figure 10: Example of Form-Factor computation from the white point on the floor to the area light source using the visibility skeleton and ray-casting with jittered sampling. The Visibility skeleton timing does not include the visibility update (about 0.13ms per link on average for this image).

Figure 11: (a) A newly inserted point (in black) and the point-polygon link to the source; the vertex points to the (b) three new negative links to the source used for the ΔB representation.

4.2.2 Multi-Resolution Link Representation

To maintain the multi-resolution representation of radiosity in the hierarchical triangulation, we require the representation of ΔB as described in Section 3.2.1, for the push phase of the push-pull procedure.

When a new point is inserted into a receiver polygon, “negative links” are created, from the source to the three vertices of the triangle containing the newly inserted point [†]. These links allow the direct computation of ΔB as follows:

$$\Delta B = B_l - \sum_{i=0..2} c_i B_{nl}^i, \quad (2)$$

[†]In practice, these are simply pointers to the previously existing links.

where B_l is the radiosity gathered from the positive link, and B_{nl}^i is the radiosity gathered from the negative links and c_i are the barycentric coordinates of point P_i . An example of negative links is shown in Fig. 11(b).

```

Gather ()
{
  for each vertex  $v$ 
     $\Delta B_v = \text{gather}(\text{positive links}_v) - \text{gather}(\text{negative links}_v)$ 
}
Push (HPolygon poly)
{
  if child(poly) == NULL return
  for each vertex  $v$  in triangulation child(poly)
     $B_v = \Delta B_v + \text{interpolation}(\text{poly}, v)$ 
  for each triangle  $t$  in triangulation child(poly)
    Push( $t$ )
}
Pull (HPolygon poly)
{
  if child(poly) == NULL
     $B_{poly} = \text{average of } B_v, \text{ for all } v \text{ vertex of poly}$ 
    return
  for each triangle  $t$  in triangulation child(poly)
    Pull( $t$ )
   $B_{poly} = \text{average of } B_t, \text{ for all } t \text{ in child(poly)}$ 
}

```

Figure 12: Gather and push-pull

The entire gather/push-pull process is illustrated in Fig. 12. Note that the field *child* of an *HPolygon* is the associated triangulation (see Fig. 5).

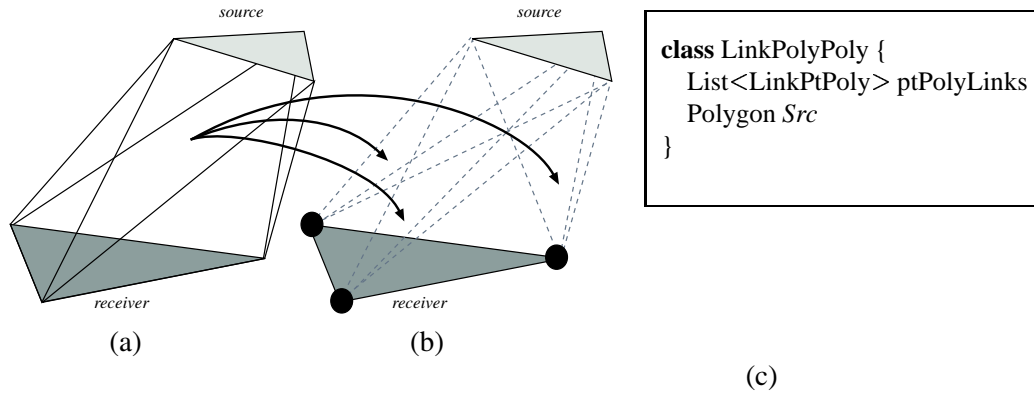

Figure 13: (a) A polygon-polygon link used to estimate illumination transfer between two polygons (b) The polygon-polygon links store pointers to the 6 corresponding point-polygon links: 3 of them (*source* → *receiver*) are shown here (c) The corresponding data structure.

4.2.3 Polygon-Polygon Links

The polygon-polygon link is used mainly to determine how well the light transfer is represented, in a manner similar to that of the links in previous hierarchical radiosity algorithms. This information is subsequently used in the refinement process as described below.

A polygon-polygon link stores visibility information via pointers to the point-polygon links (two sets of three links for two triangles) between each polygon and the vertices of the other polygon. A triangle-triangle link is illustrated in Fig. 13, with the corresponding point-triangle links from the source to the receiver.

Note that in the case of a subdivided polygon, all the neighboring triangles of a vertex v share all the point-polygon links related to v .

5 Link Refinement

Now that the link data structures have been described in detail, we can present the link refinement algorithm. Note that the process is slightly more involved than in the case of standard hierarchical radiosity, because the subdivision is not regular and the existence of the two link types requires some care to ensure that all updates are performed correctly. This section describes how the links are actually subdivided.

```

refineLinks() {
  for each polygon  $r$  and each poly-poly link  $s$  to  $r$ 
    if shouldRefine  $Link(s, r)$ 
      subdivide  $Link(s, r)$  // create the new point-poly links and
                           // new poly-poly children
      update visibility of  $Link(s, r)$ 
}

```

Figure 14: Link Refinement

5.1 Refinement overview

Consider a light exchange from a source polygon to a receiver polygon. Because we gather radiosity from the polygon at the vertices, two kinds of refinement can be necessary.

- *Source-refinement* if the radiosity variation over the source polygon is too high,
- *Receiver-refinement* if the sampling on the receiver is too coarse.

The link refinement algorithm is outlined in Fig. 14. The procedure *shouldRefine()* invokes the perceptually-based refinement criterion, which uses the visibility information contained in the extended Skeleton. This criterion is described in detail in Section 6.3. Note that the source-refinement can happen only if the source polygon has already been subdivided because of another exchange, since we compute exact point-to-area form factors.

5.2 Source and Receiver Refinement

The first type of refinement is that of a source. Consider for example Fig. 15(a), where a source-receiver link is shown. If the representation of radiosity across the source is considered insufficient for the given transfer (i.e., the variation of radiosity is too high across the source), the link will be subdivided. Note that the geometric subdivision of the source has occurred at a previous iteration, typically due to shadowing. An example is shown in Fig. 15(b). New polygon-polygon links are created between the original receiver and the sub-triangles of the

Figure 15: Source refinement: (a) original polygon-polygon link (b) One of the resulting polygon-polygon sub-links

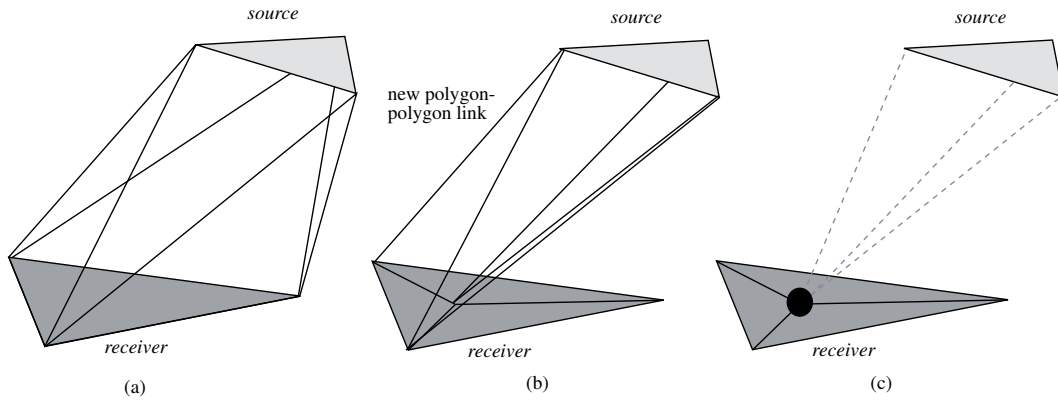

Figure 16: Receiver refinement: (a) Original polygon-polygon link (b) Insertion of a point on the receiver and one of the three new polygon-polygon links created (c) The additional point-polygon link to the source.

source. New point-polygon links are created for each vertex and each source sub-triangle, and the corresponding visibility data is correctly updated (see Section 5.3).

The second type of refinement is that of the receiver. For example, in Fig. 16, a point is added to the receiver. As a consequence, the triangulation is updated and three new polygon-polygon links are added. One of these is shown in Fig. 16(b). In addition, a new point-polygon link is created, from the point added on the receiver to the source Fig. 16(c).

5.3 Visibility Updates

Each refinement operation requires an equivalent update in the visibility information contained in the point-polygon links. We again distinguish the two main cases, source refinement and receiver refinement.

In the case of source refinement we need to update the existing visibility information contained in the new point-polygon links. Since the visibility information of such a link can be represented by the view of the source from the receiver point of the link, all that needs to be done is the update of the link with respect to the new source sub-triangles. For example, in Fig. 17(a) the original view from point P is shown in the lower part of the figure. Once the polygon-polygon link is subdivided, four new views are computed, shown in the lower part of

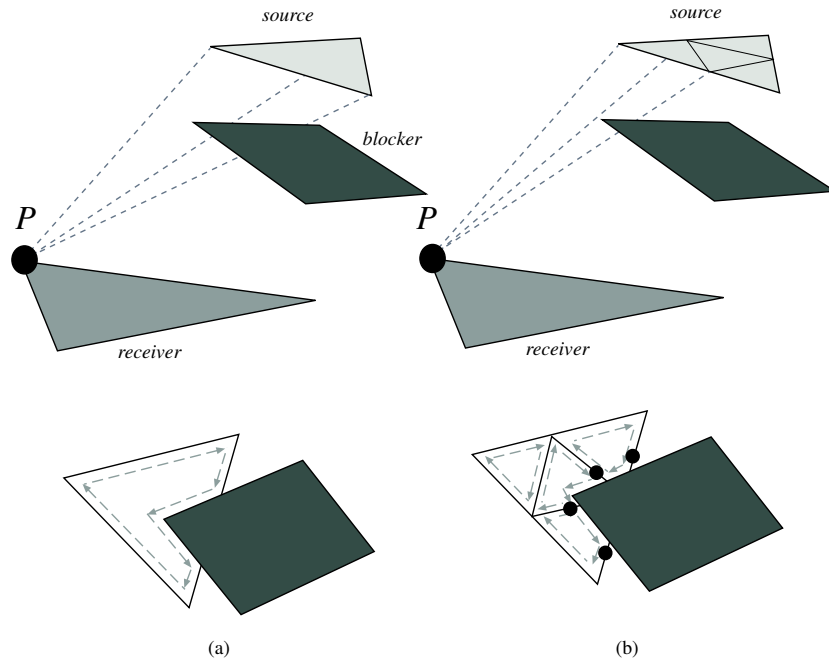

Figure 17: Source visibility updates: (a) The point-polygon link before subdivision and below the corresponding view of the source (b) The new point-polygon link due to subdivision and four new views. The black circles correspond to new nodes of the Skeleton.

Fig. 17(b). The new point-polygon links now contain the references to the skeleton arcs (swaths), corresponding to the parts of the view affected. For example the leftmost source sub-triangle is completely unoccluded from P and thus no arcs are stored. For the others, the intersections of the previously existing arcs and the source sub-triangles result in new skeleton nodes (corresponding to the black circles in Fig. 17(b)). The corresponding arcs are then subdivided. The new nodes are adjacent to these subdivided arcs. Note that all visibility/view updates are performed in 2D.

Refining a receiver is more involved. When adding a point to a polygon, a new view needs to be computed. We use the algorithm of the Skeleton construction which is robust. The only difference is that we use the blocker lists defined by the arcs stored in the initial point-polygon links instead of the entire model. Since the number of polygons in any given blocker list is relatively small, the cost of computing the new view is low. An example is shown in Fig. 18(a)-(b), where the point P is added to the receiver. In Fig. 18(b) we see the point and the new point-polygon link, and in Fig. 18(c) the newly calculated view is illustrated. The black circles correspond to newly created nodes of the skeleton.

The case of full visibility is detected using the information contained in the polygon-polygon links. The visibility update is then optimized: no new arc is computed and the unoccluded form-factor is used, thus saving time and memory.

Alternative Visibility Updates

Visibility updates could be performed using the information encoded in the Skeleton, starting from the view at one of the initial vertices, then walking to the new vertex and updating the view each time a visibility event is crossed (see Fig. 19). This method is however hard to implement, and suffers from robustness problems if the visibility events are not crossed in a coherent (if not exact) order. Moreover, the case of touching objects complicates the problem furthermore since no information can be kept while walking “under” a touching object.

Figure 18: Receiver visibility updates: (a) The initial configuration. Blocker information is contained in the source-receiver link. (b) A point is added to the receiver, creating a new point-polygon link. (c) The new view of the source computed at P . The blocker lists are updated using this computation.

Figure 19: Receiver refinement with visibility events (this solution was not implemented). (a) We start with a view at one of the initial vertices. (b) We walk across the receiver to the new vertex. Here we cross a $v_s e_b$ event. v_s begins to be hidden by the blocker. (c) We obtain the view at the new vertex. (d) In the case of touching objects, no information can be kept while crossing the interface between the two objects.

Treating Degeneracies

Subdividing along discontinuities induces degenerate viewpoints. For example in Fig. 20, we subdivide the receiver along the discontinuity $v_s e$. The view from v_r has a degenerate $v_s v_b v_r$ extremal stabbing line. To treat it coherently, we store with each vertex of the triangulation the extremal stabbing line which caused it (which is possibly null).

An alternative would have been to slightly perturb the point position to avoid those degeneracies. Two reasons have prevented us from doing so. First, discontinuity meshing allows us to delimit regions of umbra (full occlusions), regions of full visibility, and regions of penumbra. The two first types require coarser subdivision

Figure 20: Degeneracy due to discontinuity meshing. The receiver is split along discontinuity $v_s e$, causing a degenerate $v_s v_b v_r$ extremal stabbing line.

than the latter. If we perturb the point position, some regions which should have been totally in the umbra will have a very small part in the penumbra, and need more subdivision. Second, point perturbation would cause numerical precision problems.

6 Polygon Subdivision

We have now seen how link and visibility information is updated during the light propagation process. Evidently, link updates are a consequence of a *refinement* decision, based on an appropriate criterion. We have chosen to use a *perceptually-based* refinement criterion. In what follows, we first review basic concepts of perceptual mapping which we use for our refinement criteria. We next present the polygon subdivision process, and then detail the perceptually based refinement criterion which we have used for our algorithm.

6.1 Perceptual Just Noticeable Difference

The work in the field of perception provides us with two important features. First, it permits the conversion of radiometric quantities into displayable colors while preserving the subjective impression a viewer would have when observing the real scene. Second, it allows us to use error thresholds related to the error an observer is able to perceive, which are thus easy to set.

The human eye can deal with a very high dynamic range, while computer displays are usually limited to a 0 to 255 range. The eye adapts itself according to the luminosity of the scene being looked at. This explains why we are able to see dark night scenes as well as very luminous sunny scenes. The tone mapping operation deals with the transformation of high range radiometric quantities into low range display colors, while trying to provide the viewer with the same impression as the real scene. One obvious and simple method is to divide all quantities by the maximum radiosity of the scene. The problem with this approach is that if the light source intensity is halved, the scene will look exactly the same, though we would expect it to seem darker.

Ward's contrast preserving tone mapping operator [War94] deals with this problem. A simple scaling factor sf is used for the whole scene which depends on the maximal displayable luminance L_{dmax} and the world adaptation level L_{wa} which is usually the logarithmic average of the scene luminosity without primary light sources. In what follows, all intensities are expressed in *candelas/meter*² (a *candela* is a *lumen/steradian* [War94]). The scaling factor sf is then given by

$$sf = \frac{1}{L_{dmax}} \left[\frac{1.219 + (L_{dmax}/2)^{0.4}}{1.219 + L_{wa}^{0.4}} \right]^{2.5}$$

Figure 21: Effect of Ward's tone-mapping on the same scene with different light source intensities. Note how details remain perceptible while the impression of darkness or luminosity is preserved.

Fig. 21 demonstrates the effect of this operator on a given scene with different source intensities.

Once the tone mapping operation has been applied, the admissible error can be set as a given percentage of the maximum displayable intensity L_{dmax} . Psychovisual studies [GH97] have shown that the human eye is able to distinguish a difference of 2%: this is the *just noticeable difference*. We will call the allowed error ϵ_{percep} , and in practice we will use $\epsilon_{percep} = 2\%$ for all our refinement criteria.

```

subdividePolygons() {
  for each polygon  $r$  and each poly-poly link  $s$  to  $r$ 
    if shouldRefine  $Link(s, r)$ 
      refine source
  for each polygon  $r$  and each poly-poly link  $s$  to  $r$ 
    if shouldRefine  $Link(s, r)$ 
      if iteration < 3
        regularSubdivision( $r$ ) // perform grid-like subdivision
      else
        find and insert discontinuities in  $r$ 
        complete subdivision at this level // create sub-triangles in meshes
  }

```

Figure 22: Polygon Subdivision

6.2 Polygon Subdivision and Maxima Insertion

Our experiments have shown that subdividing along the discontinuities during the first few iterations results in the creation of triangles with poor aspect ratios, inducing very visible artifacts. For this reason, subdivision of the polygons is performed using a two step strategy:

- *During the first two iterations:* The polygons are subdivided in a regular grid-like manner. In particular, a regular grid is created as a function of size of the polygon being subdivided.
- *During the third and subsequent iterations:* Insert shadow discontinuities or other illumination detail. Discontinuities are added as constrained edges, and result in a modified triangulation.

This approach is similar in spirit to the (non-hierarchical) approach of Stuerzlinger [Stu94] and to the hierarchical approach of Hardt and Teller [HT96] where the discontinuity meshing is however used for display purpose only.. The polygon subdivision algorithm is outlined in Figure 22. In contrast to standard hierarchical radiosity, we cannot subdivide the polygons on-the-fly when a link needs subdivision, because polygon subdivision is not uniform and has to be performed along discontinuity curves. For this reason, we first consider all the polygon-polygon links for a given polygon to decide if it requires subdivision, and to determine which

discontinuities will be inserted. After all discontinuities for a given receiver have been inserted, the CDT is completed.

6.2.1 Inserting the Maxima

If we consider the radiosity of a light source as a function defined over a receiver, it has been shown that subdividing a mesh used to represent illumination at the maximum of the function can increase the accuracy of the radiosity solution [DF93]. We thus first compute the maxima of the unoccluded radiosity functions of the light sources before the first refinement.

The maxima are computed only for important light-transfers (estimated using the disk-disk formula [HSA91] and the perceptual metric). Given a receiver and a polygon considered as a source, we use a gradient-descent algorithm to locate the maximum. Once the maximum is found, we compute the contribution of the source at this point; if it is above ϵ_{percep} the maximum is stored to be subsequently inserted in the mesh. The radiosity of the receiver polygon is updated to take this maximum into account. That is, a gather is performed at the maximum (before a link is created from it) to obtain a better estimate of the light distribution that will be used for the first refinement.

The maxima are inserted as a separate initial step. The points of the regular subdivision which are too close to a maximum are not inserted. An example was shown in Fig. 3(b), where the maximum corresponds to the point on the lower left which is not exactly on the grid. We thus obtain nearly regular meshes with well shaped triangles.

The maxima-search process is applied iteratively to take indirect illumination into account. The insertion of maxima of indirect sources is very important for example in Fig. 25, where the table (illuminated by the lamp) is the most important light source for the upper part of the left wall.

6.3 Refinement Criterion

We distinguish two refinement criteria (or *oracles*): a radiometric criterion which accounts for the variation of the unoccluded radiosity, and a visibility (discontinuity) criterion. Moreover, the discontinuity criterion also guides the choice of the discontinuity curves to be inserted.

The radiometric oracle estimates if the linear interpolation of the light transfer is “accurate enough”. We sample the unoccluded form-factor ([BRW89] and Section 4.2.1) at the center of the patch and at the edge mid-points, and compare this to the linearly interpolated value. If the perceptually transformed difference is larger than ϵ_{percep} , we proceed with subdivision.

Figure 23: Refinement criterion geometry

The principle of our visibility oracle is to estimate (as a percentage of the maximum displayable intensity) the “shadow amount” cast by the blockers, that is the radiosity that would be transferred without the blocker.

Our refinement criterion thus has in three steps: unoccluded estimate, “shadow amount” estimate and “shadow sharpness” estimate.

Consider a receiver and a source. Recall that a source is any polygon in the scene, considered as a source at this step of the refinement process. In what follows we refer to Fig. 23, for the definition of all geometric quantities.

First, we compute an estimate of the unoccluded light transfer B_{unoc} using the disk-disk formula [HSA91]. As above, if the estimate is less than ϵ_{percep} , the link will not be subdivided.

Second, we consider each visibility event between the source and the receiver, and estimate the “shadow amount”. To do this, we estimate the part of the source potentially hidden by the blocker by using the projected diameter of the blocker on the source:

$$D_{proj}(b) = D(b) * \frac{l_2}{l_1}$$

The estimated percentage of occlusion is then

$$occlu = \frac{D_{proj}(b)^2}{Area_{source}}$$

(clipped to 1). The “shadow amount” is

$$shadow = B_{unoc} * occlu$$

If $shadow$ is below ϵ_{percep} , the visibility event is ignored.

Third, we estimate the sharpness of the shadow. The extent of the zone of penumbra is approximated by projecting the diameter of the source onto the receiver:

$$D(penumbra) = D(s) * \frac{l_1}{l_2}$$

We then estimate the lighting variation on the receiver by

$$\Delta(B) = \begin{cases} shadow & \text{if } D(penumbra) > D(r) \\ shadow * D(r) / D(penumbra) & \text{otherwise} \end{cases}$$

All the links containing visibility events with $\Delta(B) > \epsilon_{percep}$ will be subdivided. As explained above, in the first two iterations subdivision will be regular. During the third and later iterations, subdivision is performed by inserting the discontinuities with the highest $\Delta(B)$. This is the *ranking* phase of our algorithm, similar is spirit to that of [HT96].

$\Delta(B)$ is computed using l_1 and l_2 at the two extremities of the visibility event, and taking the maximum. Note that the evaluation of these oracles is very rapid since the links and events are pruned as soon as we can decide that they will not cause subdivision.

7 Implementation and Results

7.1 Implementation

We have used the C++ Visibility Skeleton implementation of [DDP97], with the extensions and changes described in Section 2. The scene polyhedra are represented using a winged-edge data-structure and a pre-processing step is performed to detect touching objects, which is a necessary step for the treatment of degeneracies.

The hierarchical triangulation has been incorporated into the same system. We use the public domain implementation of [GS85] by Dani Lischinski [Lis94] for the constrained Delaunay triangulation. Each subdivided polygon contains a triangulation `QuadMesh`.

On our test scenes, the algorithm spends most of its time on the visibility update, especially the calculation of the views at new vertices for the receiver refinement.

We have chosen not to use textures in our examples since they usually hide the accuracy of the lighting simulation.

7.2 Results

We present results for four different scenes. The first scene is a simple “Desk” scene, containing 438 polygons and two large, powerful light sources (see Fig. 24). This scene is used to illustrate the general functionality of our algorithm. The second scene contains the same geometry, but with 8 additional small, powerful light sources. The two large light sources have been turned down in intensity; we call this scene “Many Lights” (see Fig. 25). This scene shows how our approach treats the case of multiple light sources effectively. The third scene has been chosen to demonstrate the performance of our algorithm for mainly indirect lighting. We chose a common example of a bedroom lit exclusively by a small downwards-pointing, bed-side lamp. Most of the room is lit indirectly; this scene is called “Indirect” (see Fig. 27). Finally, simply in the interest of showing a completely different type of scene, we show the result of our approach on a “Village” scene, containing buildings and cars. The scene is lit overhead by a rectangular light (see Fig. 30). In what follows we present various performance statistics as well as an informal comparison with traditional (BF) hierarchical radiosity.

All times presented are in seconds on an R10000 195 MHz Silicon Graphics Onyx workstation.

Before presenting the results for the complete algorithm, we present some interesting statistics concerning the importance of accurate visibility for form-factor computation.

Importance of accurate visibility

We have run some tests with approximate visibility to judge the importance of the exact computation of the form-factors on the quality of the images. We have slightly modified our implementation to compute the form-factors using ray-casting on a jittered grid sampling of the source. The Skeleton is built used for refinement but we have subtracted this operation from the timing we provide in Table 1. As already shown in Fig. 10, this introduces a lot of error as demonstrated visually in Table 1. Moreover, the computation overhead is significant if high quality is required because at least 64 rays are needed per form-factor.

Note that the effect on the images is particularly dramatic, because the subdivision induced by the discontinuity meshing is not uniform. The thin triangles introduce very visible artifacts. These result confirm those observed in [DS96].

General Solution

The images of Fig. 24 show the initial steps of the algorithm as described previously. Fig. 24(a) is the result of three gather steps on the initial unsubdivided scene. Note that at this point we already have a (very) crude approximation to the global distribution of illumination in the scene, since the form-factors at the vertices are exact. In Fig. 24(b) we see the first step which is a regular grid together with the maxima of the light sources inserted into the mesh. Fig. 24(c) and (d) show the evolution of the algorithm after two iterations. The shaded images without the meshes are shown in (e) and (f). In (g) we show the discontinuities actually inserted. Note that these include discontinuities for all light transfers (direct and indirect) and that their number is much lower than that for a discontinuity meshing type approach.

In Table 2 we show the statistics of scenes computed using our method. For the “Desk” scene, we see that the total solution, including illumination, requires 4 minutes of computation. The quality of the solution is very high, including well-defined shadows on all surfaces. Note high quality shadows on the chairs and the table. The total number of point-polygon links is 378,746, and the number of leaf triangles is 46,058.

Treating Many Lights

One scene type for which our approach performs particularly well is that of multiple sources. This is demonstrated by our second test scene containing 10 lights and the same geometry as “Desk”. Fig. 25(a) shows an

overview of the scene as rendered by our new approach, and Fig. 25(c) shows a closeup of the floor. The shadows due to the multiple sources are well represented in the areas when appropriate. The perceptually based

ranking algorithm has correctly chosen the discontinuities that are of importance, since the combined influence of all sources is taken into account. This is shown by the small number of discontinuities present on the floor in Fig. 25(d). From Table 2 we see that 1.5 million links were used in this scene and the total computation time was 10 minutes 23 seconds.

Figure 25: Many Lights scene: (a) the final image, (b) the discontinuities actually inserted. (c) and (d) a closeup view of the floor.

As an informal comparison, for a standard hierarchical radiosity [HSA91] computation with 1.1 million links, the computation time is almost 3 hours (Table 3). In addition, the quality of the results is much lower, since many of the multiple shadows are missing (see Fig. 26). A much larger number of links would be necessary to compute an image of similar quality using hierarchical radiosity. We recognise however that an improved refinement approach (e.g., [GH96]) could potentially give better results; this is why these comparisons are “informal” and given only as an indication.

Indirect Illumination

Accurate and efficient computation for indirect lighting is another challenge for our approach. It is for this type of scene that we see the power of our accurate form-factor and discontinuity ranking method. Previous

Figure 26: Hierarchical Radiosity comparative results for Many Lights scene: (a) the final mesh, (b) a general view of the rendered scene (c) a closeup view of the floor.

<i>Scene</i>	<i># Pol.</i>	<i>1st Iter.</i>	<i>2nd Iter.</i>	<i>3rd Iter.</i>	<i>Total</i>	<i>Memory</i>	<i># of Links</i>	<i># elements</i>
Many	492	31 min	1 hr 23 min	1 hr 1 min	2 hrs 55 min	136 Mb	1,124K	34K
Bed	534	4.8min	1 hr 42 min	27 min	2 hrs 15 min	143 Mb	1,114K	51K

Table 3: Comparative Timing and memory results for the test scenes using standard Hierarchical Radiosity [HSA91] .

approaches are incapable of reaching this level of precision for secondary illumination without much more expensive calculation.

This is illustrated with our third test scene (Fig. 27 and 28), in which lighting arrives from the bedside lamp which is pointing downwards only (no light leaves from the sides or the top of the lamp). Thus everything in the room above the level of the lamp is lit indirectly.

The algorithm uses a relatively small number of point-polygon links (383,715), and manages to represent shadows generated by secondary illumination. Notice for example the shadows of the right hand lamp or the books on the far wall in Fig. 27(d); these are caused by illumination of light bouncing off the bedside table and the bed.

Again as an informal comparison, using 1.1 million links, hierarchical radiosity takes 2 hours 15 min, and produces much lower quality results (see Fig. 29(a) and (b)). Note that this is true even though the number of leaf elements used by hierarchical radiosity (51K) is actually higher than the number used by our new approach (43K triangles).

Village Scene

A final scene of a village is shown in Fig. 30, to show that the algorithm can be used for different scene types. Here the scene is lit overhead by a rectangle and also by the head and rear lights of the cars.

8 Discussion

Our new approach shows promising results in what concerns the representation of accurate shadows, in particular for the cases of multiple sources and indirect lighting. However, the method presented is not without limitations. We believe that it is worthwhile to review what we consider to be the most important limitations and drawbacks as well as the most important advantages and contributions of our approach.

8.1 Limitations

Two major limitations of this work can be identified, the first is high memory consumption and the second are numerical robustness problems of the algorithms used.

The memory usage of the skeleton data structure is high, and can often have quadratic growth in the number of input polygons, depending on how complex the visibility relations are between polygons. Even for simple environments, our method uses very large amounts of memory (see Table 2). To make our approach practical for large scenes, it is evident that we need to adopt one or a combination of the following strategies: lazy or on-demand skeleton construction, divide-and-conquer strategies (similar to e.g., [HT96]) or a clustering approach allowing a multi-resolution representation. Some ideas in these directions can be found in the Section 9 on future work.

Numerical robustness and the treatment of degenerate cases are important issues. Despite the simplicity of the construction algorithm which is based on ray-casting for node determination, degenerate cases can cause problems. As discussed in Section 2.2 we have been able to reliably treat most of these. Nonetheless, in the case of subdivision, many visual events coincide, causing problems of coherence both for the ray-tracing step (for node creation) and the adjacency determination. These problems are particularly evident in the case of view updates. A coherent and consistent treatment of degeneracies is planned, but is a research topic in itself and beyond the scope of this paper (see Section 9). Insertion of points in the mesh also causes problems, especially during subdivision due to numerical imprecision. Symbolic calculations instead of numerical intersections could potentially resolve most of these problems.

8.2 Advantages

The visibility-driven hierarchical radiosity algorithm introduced here has many advantages. First we achieve visually accurate shadows using discontinuities and exact point-to-area form-factors, for both direct and indirect illumination. The new hierarchy of triangulations data-structure, the novel two link types and the multi-resolution point-area link representation allow accurate linear reconstruction of radiosity over irregular meshes. The global treatment of visibility and discontinuities permits the definition of an efficient refinement oracle. Using a perceptually based method to estimate shadow importance, our refinement algorithm has proven to be very efficient for previously hard-to-handle scenes such as scenes lit with multiple light sources and scenes lit mainly by indirect light. As part of an informal comparison, we have seen that Hierarchical radiosity uses more computation time to produce much lower quality results, as would be expected.

Approaches such as that of [LTG93] based on discontinuity meshing have difficulty with large numbers of light sources, since the number of discontinuities becomes unmanageable very quickly. This has consequences both on computation time and on robustness in the construction of the discontinuity mesh. For similar reasons, no discontinuity-based *hierarchical* lighting algorithm has been proposed to date in which discontinuities are treated for indirect light transfers.

9 Conclusion and Future Work

We have presented a new hierarchical radiosity algorithm using the extended Visibility Skeleton. We have extended the Skeleton by replacing the n^2 table representation of the nodes and arcs by a structure of hierarchical links from polygons to polygons (and vertices to polygons). We have introduced update algorithms permitting the maintenance of consistent views at vertices added to a polygon due to subdivision, as well as the resulting sub-faces.

These extensions result in a powerful data structure which permits the computation of exact point-to-polygon form-factor for any vertex/polygon pair in the scene, and which provides detailed visibility information between any (sub)polygon-(sub)polygon pair.

We have introduced a novel hierarchical radiosity algorithm using this structure, based on a “lazy wavelet” or “sub-sampling” type multi-resolution representation. The basic data structure used is a non-uniform hierar-

chical triangulation, which consists of a hierarchy of embedded constrained Delaunay triangulations. By maintaining radiosity differences at subdivided vertices, we introduce a linear “push” step, resulting in higher quality radiosity reconstruction at the leaves. A new, perceptually-based, discontinuity driven refinement criterion has also been introduced, resulting in hierarchical subdivision of surfaces well adapted to shadow variations. The results of our implementation show that we can generate accurate high-quality, view-independent solution efficiently. The results also show that our approach is particularly well suited to previously hard-to-handle cases such as multiple light sources and scene lit almost entirely by indirect illumination.

Future Work

As was the case with the initial Skeleton work [DDP97], memory usage remains the major limitation of the visibility skeleton. It is clear that a clustering-type approach is required, which will allow us to apply our algorithm to the parts of the scene where it is required. The idea would be to compute a visibility skeleton inside each cluster and approximate visibility skeletons between clusters. The challenge is to define this approximate skeleton, since clusters are not opaque objects.

Moreover, we believe that this clustering approach is a promising way of solving the robustness problem. If the objects are grouped into clusters of a given size, it is easier to set an epsilon for the computations inside this cluster and decide which error is acceptable. In addition, since the number of objects would be almost constant inside clusters, specific verification algorithms could be applied.

The advantage of the skeleton construction is that it is local, and thus can be built in a “lazy” or even “on-demand” fashion. Using to-be-defined criteria, we could compute only the parts of the visibility skeleton related to “important” light transfers. This information could be deleted once used, thus dramatically reducing the memory requirements.

Extending the skeleton and the resulting illumination algorithm to dynamic scenes is another promising research direction. The notion of visual event can be extended to temporal visual events, for example when one line goes through five edges of the scene.

Acknowledgments

We wish to thank Seth Teller for the discussions we had about visibility, Dani Lischinski for his insights on radiosity and discontinuity meshing, and Francois Sillion and Cyril Soler for all their answers about hierarchical radiosity.
