ABSTRACT

The recently proposed coordinates-based systems for network positioning have been shown to be accurate, with very low distance prediction error. However, these systems often rely on nodes coordination and assume that information reported by probed nodes is correct. In this paper, we identify different attacks against coordinates embedding systems and study the impact of such attacks on two recently proposed representative positioning systems, namely Vivaldi and NPS. Such attacks can seriously disrupt the operations of the coordinate systems and therefore the virtual networks and applications relying on them for distance measurements.

We present a simulation study of attacks carried out by malicious nodes that provide biased coordinates information and delay measurement probes. We experiment with attack strategies that aim to (i) introduce disorder in the system, (ii) fool honest nodes to move far away from their correct positions and (iii) isolate particular target nodes in the system through collusion. Our findings confirm the susceptibility of the coordinate systems to such attacks.

1. INTRODUCTION

Recent years have seen the proliferation of application-level overlays (or overlays in short) to support many different types of applications ranging from file sharing to VoIP (e.g. [1] [2] [3] [4], etc). To achieve network topology-awareness, most, if not all, of these overlays rely on the notion of proximity, usually defined in terms of network delays or round-trip times (RTTs), for optimal neighbour selection during overlay construction and maintenance. Despite efforts to keep proximity measurements to a minimum on many overlays, the simultaneous presence of several overlays can result in significant bandwidth consumption by proximity measurements (i.e. ping storms) carried out by individual overlay nodes [5]. This problem is also compounded by dynamics in overlay membership, as measuring and tracking proximity within a rapidly changing group can prove very onerous.

To avoid such overhead, the idea of distance estimation and network positioning/coordinate systems were introduced. In such systems, the thesis is that if each node can be associated with a “virtual” coordinate in an appropriate space, distance between nodes

can be trivially computed without direct measurement. In other words, as long as a reasonably accurate position for a node can be obtained with little effort, much of the distance measurement sampling cost can be eliminated and the remaining overhead amortized over many distance predictions.

Most of the recently proposed coordinates-based systems have been shown to be accurate, achieving very low prediction error. On the other hand, a robust, stable, scalable and low overhead coordinate system can often only be realized at the expense of slow convergence times. In such a scheme, new nodes joining the system only reach a good estimate of their own coordinates after a lapse of time in the timescale of tens of seconds to several minutes. Such convergence times, which are longer than those typically achieved with individual sampling of distances by nodes, are often unacceptable for applications and this argues for a deployment of coordinate systems as a service: every node could run a coordinate system daemon at boot time which would then be capable of providing accurate coordinate estimates to applications and their overlays on request. In essence, the coordinate system could then be seen as a component of a “virtual infrastructure” that supports a wide range of overlays and applications.

But a system providing an “always-on and large scale coordinate service” would also likely be a prime target for hackers, as its disruption could result in the mis-functioning or the collapse of very many applications and overlays. Indeed, as the use of overlays and applications relying on coordinates increases, one could imagine the release of worms and other malicious software whose purpose is to attack the coordinate system. It should also be noted that as current proposals for coordinate systems assume that the nodes partaking in the system cooperate fully and honestly with each other – that is that the information reported by probed nodes is correct – this could also make them quite vulnerable to malicious attacks. In particular, insider attacks executed by (potentially colluding) nodes infiltrating the system could prove very effective. In this paper we study just how potent this danger is for the Vivaldi and NPS coordinate systems. We believe that understanding how to secure the base of distance prediction for many applications is much more critical, than detailing security of the artifacts of any particular application.

We identify three types of potential attacks against coordinate-based network positioning systems. Specifically, we study how these attacks can lead to inaccuracy of distance prediction. We analyze simple ways that allow malicious nodes to take control of the embedding coordinates system, as they are able to impose positions in the network to other honest nodes, without being detected. We also demonstrate that it is easy to perform Denial of Service (DoS) attacks on such systems. Finally, we study how conspiracy can be achieved in these systems and how much it could affect them. The “effectiveness” of these attacks on the target systems are demon-

strated through extensive simulations.

The rest of the paper is organized as follows. Section 2 provides a brief overview of the embedding coordinates systems. In section 3, we describe in more details the workings of the systems chosen for this study. We identify and classify the attacks in Section 4. We demonstrate and study the effects of these attacks, through extensive simulations, in Section 5. Section 6 concludes the paper.

2. BACKGROUND

In this section, we give a brief survey of recently proposed systems for computing coordinates to network positioning.

2.1 Fixed Landmark-based coordinate systems

These systems involve a set of landmark nodes, where other nodes compute coordinates according to measurements to these landmarks.

In Global Network Positioning (GNP) [6], the coordinates of the landmarks are first computed by minimizing the error between the measured distances and the estimated distances among the landmark nodes. An ordinary node derives its coordinates by minimizing the error between the measured distances and the estimated distances to the landmarks. GNP uses the Simplex Downhill method to compute node coordinates.

Lighthouse [7] is an extension of GNP that is intended to be more scalable. Although it has a special set of landmark nodes, a Lighthouse node that joins, does not have to query those global landmarks. Instead, it can query any existing set of nodes to find its coordinates relative to that set, and then transform those coordinates into coordinates relative to the global landmarks.

The Network Positioning System (NPS) [8] builds a hierarchical coordinate system based on GNP, where all nodes could serve as landmarks (Reference points) for other nodes.

2.2 Decentralized Internet coordinate systems

Practical Internet Coordinates (PIC) [10] is one of the recent decentralized coordinate systems using the Simplex Downhill to minimize an objective distance error function (sum of relative errors). It does not require explicitly designated landmarks. It uses an active node discovery protocol to find a set of nearby nodes to use to compute coordinates. Different strategies such as random nodes, closest nodes, and a hybrid of both, are proposed. PIC aims to defend the security of its coordinate system against independent malicious participants using a test based on the triangle inequality. However, [11] and [13] indicate that network RTTs commonly and persistently violate the triangle inequality. A security mechanism based on the fact that the triangle inequality systematically holds, may lead to degradation of the system performance when no malicious node is inside.

Vivaldi [14] is based on a simulation of springs, where the position of the nodes that minimizes the potential energy of the springs also minimizes the embedding error. Vivaldi defends against high-error nodes, but not malicious nodes. Finally, Big-Bang Simulation (BBS) [15] performs a similar simulation to calculate coordinates, simulating an explosion of particles under a force field.

3. NETWORK POSITIONING SYSTEMS IN OUR STUDY

In this paper, we chose to concentrate on two systems: NPS as a representative of the landmark-based approach; and Vivaldi as a representative of the decentralized approach.

3.1 NPS

NPS is a hierarchical design of the centralized system GNP. It aims to recover “gracefully” from either landmark failures, or situations where these special entities of the system and their network access links become performance bottlenecks. Instead of sending measurements to a central node that runs the Simplex algorithm to determine landmark coordinates (as GNP does), each NPS node runs the error minimization itself each time it measures its distance latency to landmarks, also called reference point. The main departure from GNP is that any node that has determined its position can be chosen by a membership server to be a reference point for other nodes. Actually, the membership server randomly chooses eligible nodes to become reference points when the permanent landmarks are too heavily loaded or unavailable. However, to ensure consistency, NPS imposes a hierarchical position dependency among the nodes. In the top layer of the system, denoted layer-0 (or L_0), the permanent landmarks are the fixed infrastructure used to define the bases of the Euclidean space model and can serve as reference points for the nodes in lower layers (i.e. L_1 , L_2 , etc).

Given a set of nodes, NPS partitions them into different layers. A set of 20 landmarks are placed in layer-0, and an 8-dimensional Euclidean space is used for embedding. Each node in layer L_i randomly picks some nodes in layer L_{i-1} as its reference points. The relative error of the distance prediction between a pair of nodes is defined as:

$$relative\ error = \frac{|actual - predicted|}{\min(actual, predicted)}$$

In [8], authors argue that a 3-layer NPS system is already very accurate and can support more than 2 billion nodes.

NPS includes a strategy for mitigating the effects of simple malicious attacks. Indeed, malicious nodes could potentially lie about their positions and/or inflate network distances by holding onto probe packets. The basic idea is to eliminate a reference point if it fits poorly in the Euclidean space compared to the other reference points. Each node, when computing its coordinates, based on different reference points measurements, would reject the reference that provides a relative error significantly larger than the median error of all reference nodes. Specifically, assume there are N reference points R_i , at positions P_{Ri} , and the network distances from a node H to these are D_{Ri} . After H computes a position P_{Hi} based on these reference points, for each R_i , it computes the fitting error E_{Ri} as $\frac{|distance(P_{Hi}, P_{Ri}) - D_{Ri}|}{D_{Ri}}$. Then the requesting node, H , decides whether to eliminate the reference point with the largest E_{Ri} . The criterion used by NPS is that if (1) $max_i E_{Ri} > 0.01$ and (2) $max_i E_{Ri} > C \times median_i(E_{Ri})$, where C is a constant, then the reference point with $max_i E_{Ri}$ is filtered (i.e. H tries to replace it by another reference point for future repositioning).

3.2 Vivaldi

Vivaldi is fully distributed, requiring no fixed network infrastructure and no distinguished nodes. A new node computes its coordinates after collecting latency information from only a few other nodes. Basically, Vivaldi places a spring between pairs of nodes (i, j) with a rest length set to the known (measured) RTT (L_{ij}) between them. The current length of the spring is considered to be the distance between the nodes as estimated in the coordinate space. The potential energy of such a spring is proportional to the square of the displacement from its rest length: the sum of these energies over all springs is the error function that Vivaldi nodes try to minimize.

An identical Vivaldi procedure runs on every node. Each sample provides information that allows a node to update its coordinates.

The algorithm handles high error nodes by computing weights for each received sample. Each sample used by a node i , is based on measurement to a node j , its coordinates x_j and the estimated error reported by j , e_j . The relative error of this sample is then computed as follows:

$$e_s = | \|x_j - x_i\| - RTT_{measured} | / RTT_{measured}$$

The node then computes the sample weight balancing local and remote error: $w = e_i / (e_i + e_j)$, where e_i is the node's current (local) error. This sample weight is used to update an adaptive timestep, δ defining the fraction of the way the node is allowed to move toward the perfect position for the current sample: $\delta = C_c \times w$, where C_c is a constant fraction < 1 . The node then updates its local coordinates as follows:

$$x_i = x_i + \delta \cdot (RTT_{measured} - \|x_i - x_j\|) \cdot u(x_i - x_j)$$

where $u(x_i - x_j)$ is a unit vector giving the direction of i 's displacement. Finally, it updates its local error as $e_i = e_s \times w + e_i \times (1 - w)$.

Vivaldi considers a few possible coordinate spaces that might better capture the underlying structure of the Internet. Coordinates embedding maps the network distances into different geometric spaces, for instance 2D, 3D or 5D Euclidean spaces, spherical coordinates, etc. Vivaldi also introduces the *Height model*, consisting in an Euclidean coordinate space augmented with a height vector. The Euclidean portion models a high-speed Internet core where latencies are proportional to geographic distance, and the height vector models the time it takes packets to travel the access link from the node to the core. In [14], authors show that the more dimensions a Euclidian space has, the more accurate the Vivaldi system is. Moreover, results prove that height vectors perform better than both 2D and 3D Euclidean coordinates.

4. THREATS AND ATTACKS CLASSIFICATION

We classify attacks and identified threats that malicious nodes may seek to carry out on positioning coordinate-based systems. We consider malicious nodes that have access to the same data as a legitimate user. This means that participants are not completely trusted entities, or that malicious nodes have the ability to bypass any authentication mechanisms. Malicious nodes are able to send misleading information when probed, or send manipulated information after receiving a request or affect some metrics observed by chosen targets. The main classes of attacks on positioning system behavior are:

1. **Disorder:** the main goal of this attack is to create chaos as a form of denial of service (DoS) attack. This results in high errors in the positioning of nodes, or the non-convergence of the algorithm. The attack consists only in maximizing the relative error of nodes in the system, either passively by not cooperating or falsifying its coordinates or by actively delaying probes.
2. **Isolation:** where nodes would be isolated in the coordinate space. The attack could target a particular node, in order to convince the victim that it is positioned in an isolated zone of the network. The final goal of such attack can be, for instance, obliging the victim to connect to an accomplice node as the closest node in that zone, in order to perform traffic analysis or packets dropping, man in the middle attacks, etc. One way a malicious node can conduct this attack is to delay probes sent by the victim, and to falsify its proper coordinates, so that the victim's computed coordinates are set to a value large enough, to be far from other nodes.

3. **Repulsion:** where a malicious node would convince its victims that it is positioned far from other participating nodes in order to reduce its attractiveness, and then, for instance, alleviate its resource consumption by not cooperating in the application progress. Ways to perform such attacks are to make its conditions (performance, position) seem worse than they actually are. This is accomplished by means of delaying measurement probes and/or by manipulating the coordinates transmitted to other nodes or to a set of central entities, such as landmarks.
4. **System Control:** This attack is possible on coordinates-based systems that allow "normal" nodes to be considered as landmarks, i.e. most of the existing systems except the centralized systems. In hierarchical systems for example, such as NPS, nodes would try to get higher in the hierarchy in order to fool and influence the maximum number of correct nodes.

The classes of attacks briefly described above can either be carried out by malicious nodes in an independent manner or as a conspiracy created by colluding nodes. Collusion is likely in a scenario where attack propagation happens through the now well tested means used in today's DDoS attacks (e.g. worms, etc).

It should be noted that all attacks, be they explicitly aimed at disrupting the whole system or skew the coordinates of a single node will often result in some distortion of the coordinate space. This is because of the possible cooperation between the nodes that will act as a catalyzer to the propagation of errors to other (non directly targeted) nodes.

5. PERFORMANCE EVALUATION

5.1 Performance Indicators

We use the relative error (defined in section 3) as our main performance indicator. We compute the average relative error over all nodes to represent the accuracy of the overall system. Since our focus is on measuring the impact of malicious nodes on the system, we also introduce the *relative error ratio* (called Ratio), which is the relative error measured in presence of malicious nodes normalized to the performance of the system without cheats used as the best case scenario (i.e. $error_ratio = error / error_{ref}$). Obviously, a value for the error ratio above 1 indicates a degradation in accuracy.

As the worst case scenario, we also compute the relative error of a coordinate system where nodes choose their coordinates at random. In this random scenario, all nodes choose their coordinate components randomly in the interval $[-50000, 50000]$ (for each dimension of the coordinate).

5.2 Simulation set up

We used the "King" data set to model Internet latencies based on real world measurements. This dataset contains the pair-wise RTTs between 1740 Internet DNS servers collected using the King method [17]. This was used to generate a topology with 1740 overlay nodes, from which we derived various group sizes by picking nodes at random (unless otherwise stated, in the simulations, the group consists of all the 1740 nodes). Each scenario was repeated 10 times with the malicious nodes selected at random within the group. We consider groups with 10%, 20%, 30%, 40%, 50% and 75% of malicious nodes. In view of the infection rates of recent worm epidemics, we believe these values to be realistic, both during and for a long time after an outbreak.

For the Vivaldi simulation scenarios, we used the p2psim discrete-event simulator [16]. Each Vivaldi node has 64 neighbours (i.e.

is attached to 64 springs), 32 of which being chosen to be closer than 50 ms. The constant fraction C_c for the adaptive timestep (see section 3.2) is set to 0.25. These values are those recommended in [14]. The system is considered to have stabilized when all relative errors converge to a value varying by at most 0.02 for 10 simulation ticks. We observed that Vivaldi without malicious nodes always converged within 1800 simulation ticks, which represents a convergence time of over 8 hours (1 tick is roughly 17 seconds). Unless otherwise stated, our results are obtained for a 2-dimensional coordinate space.

For NPS, we developed our own event-driven network simulator, based on the description of the protocol in [8] and a reference implementation of the protocol¹. Unless otherwise stated, as recommended in [8], we considered an 8-dimensional Euclidean space for the embedding. In layer-0, a set of 20 well separated permanent Landmarks are chosen. 20% of nodes are randomly chosen as reference points, in each subsequent layer. For the security mechanism of NPS, the sensitivity constant C was set to 4.

Finally, in this paper, we consider all the attacks in an “injection” context, where the malicious nodes are introduced in a system that has already converged. This is in contrast with a “genesis” attack where the malicious nodes are present from the system’s creation time (which we studied in [9] for Vivaldi). The former is more realistic in a practical setting, and reflects the emergence of threats carried out by malware in the current Internet.

5.3 Attacks on Vivaldi

5.3.1 Disorder Attack

We first discuss ways to achieve Disorder attacks in Vivaldi. As it is a fully-distributed algorithm relying on cooperation of nodes in order to ensure accuracy of the computed coordinates, it seems easy to fool honest nodes. The disorder attack has no specific objective, but false coordinates computations and high positioning error. When solicited, a malicious node sends a randomly selected coordinate x_j , associated with a very low error, $e_j = 0.01$. Moreover, each node’s measurement is delayed by a randomly generated value in [100..1000] ms. In this first scenario, it is not necessary to care about lie consistency, as Vivaldi uses error weights sent along with the responses to probes to adjust the adaptive timestep. Even if the measured distance $RTT_{measured}$ to malicious node j is not consistent with the coordinates x_j , the victim i would consider itself as a high error node, and would try to adjust its coordinates by a great adaptive timestep value, due to the fact that j sends a low error.

Figure 1 depicts the relative error ratio variation in function of time, for our full set of 1740 nodes, representative of the impact of the malicious nodes on the system. It is clear that enough attackers can quickly destabilize a converged system and seriously reduce the system accuracy. It is interesting to note that, in the presence of enough malicious nodes, despite the system converging in the sense that the relative errors at each node stabilize, these errors are so high that a great variation of the coordinates of a node barely affects the associated error. In other words, the coordinates of the nodes keep showing great variations and do not stabilize but the error introduced by such constant movement is stable because there is already so much chaos in the system. In essence, the system is deemed to converge because it doesn’t get any better nor any worse.

Figure 2 shows the cumulative distribution of the relative error of the victims of an injected disorder attack. We clearly see that from 30% of malicious nodes the impact on the system can be considered

as very serious with many nodes seeing a large increase in their relative errors. For a proportion of 50% or more malicious nodes, the system collapses with over half of the honest nodes computing coordinates that are similar or worse than if chosen randomly.

Figure 1: Injection of Disorder Attackers on Vivaldi: average relative error ratio.

Figure 2: Injected Disorder attack on Vivaldi: CDF of relative error at simulation tick = 5000

Figure 3 represents the impact of the space dimension on the attack. In this figure, the average relative error of honest nodes is measured after re-convergence. We see that the more accurate the Vivaldi system is in the absence of malicious nodes, the more vulnerable it is to the disorder attack. This is because the variation of more coordinates components for a point in a larger space results in higher displacement in that space. This observation is compounded for the 2-dimensional space augmented by a height as a variation of the height yields a greater effect on the node displacement. We also observe that in most cases, Vivaldi with half the population of malicious nodes is worse than a random coordinate system.

Figure 4 shows the impact of the attack as a function of the system size as measured a long time after the attack started. We see that a larger system is more difficult to impact for a same proportion of attackers. This is consistent with the fact that a larger Vivaldi system is more accurate, but also establishes that Vivaldi finds increased strength in a larger group. Put simply, this is because as one increases the number of springs in the system, the energy needed to disrupt it is higher. In our case, a larger group means more “good” forces to counteract and dissipate the effect of the malicious ones.

5.3.2 Repulsion Attack

In this scenario, malicious nodes are trying to isolate some nodes in the network, either by repulsing a set of targets away from other

¹The authors would like to thank Prof. Eugene Ng for sharing his code.

Figure 3: Injected Disorder Attack on Vivaldi: Impact of space dimensions

Figure 4: Injection of Disorder Attackers on Vivaldi: Impact of system size on the attack.

nodes in the coordinate space, or by repulsing all requesting nodes away from a selected target. The first attack consists in fixing coordinates where to isolate all requesting nodes, say X_{target} . It is important to notice that this value is set high enough to allow lie consistency. This means that the predicted distance after the lie should be equal to the measured distance. In fact, since we assume that a malicious node cannot shorten a distance measurement, but can however delay it, we must set the coordinates of both the victim and the malicious node to be consistent with this fact. Although for most network positioning systems, application probes are used, for generality purposes we design and test the attacks assuming ICMP ping probes. We assume here that malicious nodes know the current coordinates of their targets, $X_{Current}$, by means of previous requests for example. Malicious nodes are then able to compute the needed RTT that are consistent with the lie,

$$RTT = (\|X_{target} - X_{Current}\| / \delta) + \|X_{target} - X_{Current}\|$$

and to delay the measured RTT by:

$$RTT_{needed} - 2 \cdot (ReceivedTimestamp - SendTimestamp).$$

Each malicious node is selecting a random coordinate that is far away from the origin.

Figure 5 shows the cumulative distribution function of the measured average relative error after convergence in a repulsion attack. The gentler slope of the curves indicates that the impact of this type of attack is greater than in the case of a disorder attack (see fig. 2). This is because a repulsion attack is more structured and more consistent than a disorder attack, since the chosen target coordinate is always the same for every victim-attacker pair.

We study the effect of space dimension on the attack in figure 6.

Figure 5: Injected Repulsion Attack on Vivaldi: CDF of relative error.

Again, the results confirm that the more accurate the system is without malicious nodes, the more vulnerable it is to attacks, which highlights a fundamental trade-off between accuracy and vulnerability.

Figure 6: Injected Repulsion Attack on Vivaldi: impact of space dimensions.

So far, the repulsion attack consisted in each attacker attacking every other node. Figure 7 shows the effect of a modified repulsion attack where each attacker independently attacks a subset of the other nodes. Each attacker chooses its own target subset independently, along with their target coordinate values. However, the target subset size is fixed and equal for all attackers. We see that small subsets chosen independently result in a less effective attack and that there is no great difference in effectiveness when the set of attackers constitutes less than 30% the population. This can be explained by the fact that in such conditions the attack gets “diluted”, giving the system plenty of opportunity to correct itself through nodes that are under no, or very little, attack.

Figure 8 shows the response of a system under injection repulsion attack as a function of system size. As in the case of a disorder attack, larger systems reduce the impact of the attack. However, because a repulsion attack is much more consistent than a disorder attack, the system is less effective at countering the effects. This is why we observe higher values for the average relative error and a much gentler slope of the curve than in figure 4.

5.3.3 Colluding Isolation attack

This is a repulsion attack where the attackers behave consistently in a collective way. They could, for instance, try and move all honest nodes consistently away from a same designated target node. That is, they agree on a distance from the chosen node for each vic-

Figure 7: Injected Repulsion Attack on subsets of target nodes.

Figure 8: Injection Repulsion Attack on Vivaldi: effect of system size

tim and collectively and consistently direct victims towards their designated coordinate.

Figure 9 depicts the effects of a colluding isolation attack on the system. The salient result is that the system can quickly become worse than a random coordinate system. Indeed, from 30% of malicious nodes in the system, the accuracy becomes equal or worse than if nodes chose their coordinates at random. This clearly demonstrates that colluding attacks are very potent due to their better structure and can have a great adverse impact on overall system performance.

Figure 9: Colluding isolation Attack on Vivaldi: average relative error ratio

Another type of colluding isolation attack is for the attackers to set their coordinates in a remote area of the coordinate space (so that they are clustered in that area) and then to choose a victim

target node and convince it that its own coordinate is within the attacker cluster. The target coordinate is set before the attack begins and agreed by all attackers.

We observe in figure 10 the variation of the relative error of the

Figure 10: Colluding Isolation attack on Vivaldi: target relative error

target through time. We see that the first type of colluding isolation attack (consisting in repelling all other honest nodes from a chosen target) is more effective than trying to lure a target into a remote area of the space. Intuitively, this is because much more error is introduced in the system when more nodes are pushed away from their correct position, thus resulting in more distortion of the coordinate space with greater repercussion on the final position of the target nodes. This is indeed confirmed by the results of figure 11 that depicts the cumulative relative error for the nodes in the system under both types of colluding attacks.

Figure 11: Colluding Isolation Attack on Vivaldi: CDF of relative errors.

5.3.4 Combined attacks

In the context of system offering an always-on and large scale coordinate service, it is plausible to assume a constant and permanent low level of malicious nodes. Indeed, in the previous sections we have examined the effects of attack outbreaks. But in the wild, as has already been observed after major worm outbreaks and security warnings, once an outbreak has been contained and resolved, one can expect that some small portion of the systems are not upgraded for a very long time after the release of the necessary patches. This is especially true in the case of systems that are under many different administrative controls (as is the case for home personal computers). Figure 12 shows the impact of such low level of combined attacks on Vivaldi, where colluding nodes implement

strategy 1 of the colluding isolation attack. In these combined attacks, the percentage of malicious nodes of each type is the same. This figure shows that fairly low level of malicious nodes can still have a sizeable impact on the overall system performance, which, in turn, indicates that return to normality after an attack may take an extremely long time, if at all possible.

Figure 12: Combining attacks on Vivaldi: impact on convergence.

Finally, figure 13 confirms that larger systems are more resilient and recover better than smaller ones.

Figure 13: Combined attacks on Vivaldi: effect of system size.

5.4 Attacks on NPS

We experimented the NPS system in both a secure and non secure version. Unless stated otherwise, the security mechanism is set on. Note also that we consider the ideal, hypothetical case where the landmarks are highly secure machines that never cheat. The results we present in the following sections can therefore be considered as best case scenarios from a security point-of-view, as the impact of attacks could be much more severe should our security of landmark hypothesis not hold.

5.4.1 Injection of independent Disorder attackers

In this first attack, when malicious nodes are chosen as reference points by the membership server (or when an already active reference point gets infected by malware), they perform simple attack that consists in transmitting the correct coordinates of the (malicious) reference point to the victim, and delaying measurement probes without caring about lie consistency. Figure 14 depicts the average relative error variation in function of time, while injecting after convergence of the system, a percentage of malicious nodes. When the malicious reference node detection mechanism is off, we

Figure 14: Injection of Independent Disorder attackers (No prevention): average relative error.

notice the sharp climb in relative error when 20% of malicious nodes join the system. The accuracy of NPS is destroyed when cheating nodes get introduced in layer 1 of the measurement hierarchy. On the other hand, the malicious reference node detection mechanism is shown to be highly effective in combating such a malicious population of up to more than 30% of the overall population. However, a population of 40% or more malicious nodes in the system defeats the NPS security mechanism. This can be explained by the fact that the security mechanism relies on simple statistical properties of the observed errors (i.e the median) to filter out perceived outliers. In the presence of enough malicious nodes serving as reference points, the computation of the median itself gets skewed sufficiently that malicious behaviour is assimilated to normal behaviour. The cumulative distribution function of the measured average relative error shown in figure 15 confirms previous results. The gentler slope, and heavy tail feature, of the 40% and 50% curves when security is on indicates the impact of the attack when enough malicious nodes are introduced in the system. We observe that when introducing 40% of malicious nodes, only 50% of honest nodes would re-converge to a relative error less than 0.5.

Figure 15: Injection of Independent Disorder attackers: CDF.

Figure 16 shows the effect of space dimension when NPS is subjected to a simple disorder attack. Just as in the Vivaldi case, this experiment proves again that the more accurate the system is without malicious nodes, the more vulnerable to attacks it is. In particular, we observe that with more dimensions used in the coordinate space, the NPS system is much more vulnerable to a smaller portion of malicious nodes. We observe that systems running with 6 and 8 dimensions still can prevent against a minority of malicious nodes, whereas a simple attack can destabilize a 10 or 12-dimensions NPS

Figure 16: Injection of Independent Disorder attackers: Impact of dimensionality.

system more easily. In the later cases, when malicious nodes only constitute 20% of the population, the relative error climbs to more than 1. From 50% of malicious nodes injected in the system, the accuracy becomes equal or worse than if nodes chose their coordinates at random. This is explained by the fact that the more dimensions are used, the more “chances” malicious nodes get to become reference nodes, creating greater confusion among the honest nodes that depend on them in the layers below. Moreover, as in the Vivaldi case, more dimensions result in greater displacement in coordinates space for the victim.

5.4.2 Injection of Anti-Detection Naive Disorder Attackers

In this section, we consider an attack whose primary strategy is to try and defeat the NPS security mechanism. To this end, attackers will lie consistently about their position and inflate network distances by that corresponding amount, while paying particular attention that the relative error computed by the victim is lower than 0.01. Doing so essentially negates the very first condition checked to detect malicious nodes (see section 3.1), in effect shutting down detection of the attackers.

First, we consider that malicious nodes know their targets’ coordinates with a probability $p = 1/2$. We discuss next the effect of coordinates information on the efficiency of the attack. The target coordinates information allows first to better estimate the distance between the target and the attacker and second to compute the direction defined in the coordinate space by the nodes themselves. When not available, the malicious node sets a random direction and estimates the distance between itself and the target as $ReceivedTimestamp - SendTimestamp$.

As illustrated in figure 17, the attack consists in delaying the victims’ probes by $\|P'_{Ri} - P_{Ri}\| = d'$ such that $\|P'_{Ri} - P_{Ri}\| \gg d$ and then send coordinates P''_{Ri} such that $\|P''_{Ri} - P_{Ri}\| < 0.01 \|P'_{Ri} - P_{Ri}\|$.

Figure 17: Anti-Detection NPS attack

It is easily shown that $E_{Ri} < 0.01 \Rightarrow d'' > \frac{\alpha+1.99}{0.01} \cdot d$ with $\alpha d = d'' - d'$.

To make the attack harder and make the security mechanism of

NPS behave in more realistic way, we add a probe threshold condition to each probe, such that a probe would be considered by the requesting node as suspicious if the RTT it measured was above that threshold. Such probes are then discarded. In the following simulations, the probe threshold is set to 5 seconds. In a first scenario, we consider malicious nodes that ignore this probe threshold, yielding a so-called naive anti-detection disorder attack.

In figure 18, we observe the average relative error variation after injection of malicious nodes in a converged NPS system. We see that this attack has a bigger impact on the whole system than the simple disorder attack (see figure 14), causing greater average relative errors. We also observe that the attack is very effective at defeating the security mechanism, with the security-protected relative errors only trailing marginally the errors observed when no security mechanism but the probe threshold is employed. This is despite the attacker guessing half of the time and could therefore appear surprising. However, the reader should note that the NPS security mechanism discards at most one malicious reference point at each positioning (i.e. the one yielding the greater error), giving the malicious nodes potentially several reprieves on bad guesses.

Figure 18: Injection in NPS of Anti-detection naive attackers: impact on convergence.

As for the Vivaldi system, we note that in presence of only a minority of malicious nodes, despite the system converging in the sense that the relative errors at each node stabilize, these errors are so high that a great variation of the coordinates does not affect the associated error.

We measured the impact of dimensionality and group size on the effectiveness of this attack and found the now expected results that higher precision (i.e. higher dimensionality) was more affected while larger groups present a better immunity.

More interesting in this attack is the effect the knowledge of the attacker has on its effectiveness. In figure 19, we show the relative error ratio for various probabilities that the attacker knows a victims’ coordinates prior to striking. We see that in the presence of a small malicious population, full knowledge of victims’ coordinate can almost triple the effectiveness of the attack compared to the pure guess work case. However, as the population of malicious nodes grows, the benefits of more knowledge diminish. This confirms again that, regardless of the sophistication of the attack, the NPS security system soon gets overwhelmed when the population of malicious node exhibits a certain critical mass. As figure 20 shows by representing the ratio of malicious nodes filtered to the overall number of filtered nodes by the security mechanism, this critical mass is about 20% (about half the needed population of malicious node compared to the simple disorder attack). Furthermore, this figure also confirms that, as more and more malicious nodes are

able to operate in all impunity, the errors they introduce in the positioning of honest nodes result in higher false positive rates with the security mechanism filtering out more and more (mis-positioned) honest reference points. But because at most one reference point gets filtered per positioning, these false positives actually create some extra protection for the malicious ones.

Figure 19: Injection in NPS of Anti-detection naive attackers: effect of victims coordinates knowledge.

Figure 20: Injection in NPS of Anti-detection naive attackers: effect of victims coordinates knowledge on the ratio of filtered malicious nodes over the overall filtered nodes.

5.4.3 Injection of Anti-Detection Sophisticated Disorder Attackers

We now present a modification of the previous attack where the malicious nodes make an attempt to not only defeat the NPS mechanism but also avoid detection by the probe threshold mechanism. To do so, an attacker will only interfere with the positioning process of nodes known, or believed, to be nearby. Indeed, if we recall the discussion in section 5.4.2, with a probe threshold of 5 s and $\alpha = 2$, then $d'' + d < 5s \Rightarrow d < 25ms$ in order to avoid detection by the NPS security system, d being the real distance between an attacker and its victim. As this attack is bound to be less detectable by the security mechanisms than the previous one which already yielded small differences between the "security on" and "security off" cases, only results in the presence of these security mechanisms are presented here. Unless stated otherwise, the attackers guess the position of their victims half of the time.

Figure 21 shows the cumulative distribution function of the relative errors in a system under anti-detection sophisticated disorder attack. Clearly, this attack is devastating on the overall accuracy of the coordinate system, despite the attackers being more selec-

tive of their victims. This is because, even though the errors introduced by each attacker are smaller than in the naive case (nodes that are closer can only be "pushed" less aggressively if the attacker is to avoid detection), these errors are allowed to permeate unchallenged through the system, propagating more widely through the undetected mis-positioning of honest nodes. We observed that in the system without malicious nodes, the mean relative error converged towards a value of about 0.4. Here we see that as little as 10% of attackers leave over 60% of the overall population worse off than the average node in a clean system. We also observed that compared with the more naive version of this attack (figure 18), the more sophisticated version induces higher average errors.

Again, better accuracy (i.e. higher dimensionality) and smaller group sizes were observed to be more sensitive to the attack.

Figure 21: Injected Anti-detection Sophisticated attacks on NPS: CDF.

Figure 22 shows the impact of the attacker's knowledge on the attack. By going from pure guessing to full knowledge (i.e. attacking only victims whose coordinate are known), an attacker can reduce by half its chances of being caught. We also see that the intrinsically more cautious strategy of this attack dramatically reduces the chances of an attacker being detected compared with the naive attack case (figure 20), especially when malicious nodes represent a smaller proportion of the population and operate without much exact coordinate knowledge of their victims. Indeed, for the case where the attacker never knows exactly the coordinate of their victims, figure 22 shows that over 75% of all detections are false positives for attackers populations of 10% and over of the group.

Figure 22: Injected Anti-detection Sophisticated attacks on NPS: effect of victims coordinates knowledge on the ratio of filtered malicious nodes over the overall filtered nodes.

5.4.4 Injection of Colluding Isolation attackers

In a colluding isolation attacks, the malicious nodes cooperate with each other and behave in a correct and honest way until enough of them become reference points at the same layer. Once at least a minimum number of malicious reference points has been reached (in our simulation this number is set to 5), these attackers identify a common set of victims. When involved in the positioning of any other nodes, the attackers do not cheat; while when dealing with a target node, they agree to pretend they are all clustered into a remote (far away) part of the coordinate space and carry out a naive anti-detection attack on the victim. The goal of this attack is to push the victims into a remote location at the "opposite" of where the attackers pretend to be, thus isolating the victims from all the other nodes (in the coordinate space). The other main idea behind this attack is that by acting in a consistent way as a group, the attackers can maybe avoid detection by influencing the value of the median relative error (condition 2 of the NPS security mechanism – see 3.1). Also, as already mentioned, even if detected, at most one attacker would be filtered at each positioning, giving the others more opportunities to act.

We consider 2 scenarios for this attack. The first scenario consists in experimenting with a 3-layer NPS system, i.e. a system with the landmarks in layer-0, 20% of nodes serving as reference points in layer 1, and the rest of the nodes in layer-2. The second scenario is aimed at observing the propagation of errors through different layers and uses a 4-layer NPS system, with 2 layers (layer-1 and layer-2) containing 20% of the nodes acting as reference points.

Figures 23 and 24 show the cumulative distribution function of the relative errors in a 3-layer and 4-layer NPS system (respectively) under this colluding isolation attack. We observe a striking difference of impact depending on the structure of the NPS system. Indeed, the overall accuracy of a 3-layer system is much less unaffected than the accuracy of a 4-layer system. On the one hand, it is worth remembering that, in the 3-layer system, non victim nodes do not see any degradation of the accuracy of their positions (compared to a clean system), because they observe an honest behaviour from the attackers. This means that the overall degradation in accuracy is caused by the mis-positioning of the victims only. Hence, the perceived little impact of the attack depicted in figure 23 actually tends to indicate that the attack is very effective on the victim.

On the other hand, in a 4-layer system, some of the victims may be unwittingly selected by the membership server to act as layer-2 reference points. The position errors inflicted on these nodes are then propagated through the rest of the system, resulting in an amplification of the errors from layer to layer. This is demonstrated in figure 25 that shows the average relative error of layer-2 and layer-3 nodes in clean 3-layer and 4-layer systems respectively, as well as the average relative error observed by layer-2 targets and layer-3 nodes in corrupted systems with a population of 20% of malicious nodes. From this figure, it is clear that the impact of layer-1 cheats on layer-2 victims is independent of the system structure (the curves are similar), layer-3 nodes of an attacked 4-layer system experience the worse mis-position. This propagation and amplification of the errors in this 4-layer system can be seen as a system-control attack (see 4).

Finally, as in the Vivaldi case, we measured the impact of several small population of attackers which concurrently carry out all the previous attacks. This is reminiscent of a situation where some nodes are still misbehaving for some time following the release of patches and updates after a major outbreak of malware. Again, we see that attacks can have long lasting consequences on the operation of the coordinate system.

6. CONCLUSION

In this paper, we have studied various types of attacks on two prominent coordinate system proposals. One of our salient findings is that larger systems are consistently more resilient than smaller ones. Given the observation in [14] and [8] that larger systems are more accurate and the well known fact that larger systems converge slower at start-up time, there seems to be a compelling case for large-scale coordinate systems to be built as a virtual infrastructure service component. The paradox is of course that always-on, large scale systems supporting many different applications will always attract more attacks than systems with a smaller reach, while the large size of the system itself would act as a particularly good terrain to create especially virulent propagation of the attack.

Our results also show that there is an intrinsic trade-off to be made between accuracy and vulnerability. Indeed, we have shown that the more accurate the system for a given system size, the more susceptible it was to a same proportionate level of attack.

Also, we have shown that while an attack is in full swing, the performance of the coordinate systems (and of the applications it supports) can easily degrade below that of a system where coordinates are chosen randomly, whilst the aftermath of an attack could have very long lasting effects on the system due to a small number of remaining malicious nodes.

We have also shown that infrastructure-based systems can, under some well chosen attack strategies, be as vulnerable than those based on the peer-to-peer paradigm. Furthermore, the security mechanisms that have been proposed to date to defend against malicious nodes are clearly rather primitive and still in their infancy and def-

initely cannot defend against all types of attacks.

In our future work, we will concentrate on designing generic defense and security mechanisms to protect coordinate-based systems from large-scale malicious attacks. This work will be guided by the understanding of attack mechanisms and of their consequences on the coordinate systems gained from the study presented in this paper.
