Abstract. Adaptation is a task of case-based reasoning systems that is largely domain-dependant. This motivates the study of adaptation knowledge acquisition (AKA) that can be carried out thanks to learning processes on the variations between cases of the case base. This paper studies the representation of these variations and the impact of this representation on the AKA process, through experiments in an oncology domain.

Introduction

Case-based reasoning (CBR) aims at solving a target problem thanks to a case base. A case is the description of a problem-solving episode which can be generally seen as a pair (problem, solution). A CBR system selects a case from the case base and then adapts the associated solution. Adaptation is a difficult task since it requires domain-dependant knowledge that needs to be acquired. The goal of adaptation knowledge acquisition is to detect and extract this knowledge. Some approaches have proved successful in learning such adaptation knowledge from the case base.

Our hypothesis is that this learning task can be improved by choosing an appropriate representation of the variations between cases in the case base. Introducing general knowledge on variations enables the extraction of different types of adaptation rules. In particular, a limited number of general adaptation rules may be presented to the analyst for validation. Afterwards, these rules are helpful to structure a set of specific adaptation rules.

The paper is organized as follows. Section 1 defines general notions on CBR that are used in the rest of the paper. The AKA approach of [6] is summarized in section 2. It involves some knowledge representation and learning issues — representing and learning variations and adaptation rules — that are addressed in section 3 independently of the case representation formalism. Then, this general framework is applied to an attribute-constraint formalism for representing cases (section 4). Section 5 presents some experiments in an oncology domain to
validate our hypothesis on the usefulness of choosing an appropriate representation of the variations. Section 6 discusses this work by comparing it to related work. Finally, section 7 concludes and points out some future work.

1. Definitions

Let $L_{pb}$ and $L_{sol}$ be two languages. A problem (resp. a solution) is by definition an element of $L_{pb}$ (resp. of $L_{sol}$). The existence of a binary relation $\sim$ on $L_{pb} \times L_{sol}$ is assumed, but not completely known in general. $Sol(pb)$ is a solution of $pb$ if $pb \sim Sol(pb)$. A case is a pair $(pb, Sol(pb))$ such that $pb \sim Sol(pb)$. The case base is the finite set of available cases, called source cases and denoted by $(srce, Sol(srce))$. CBR aims at solving a target problem $tgt$ thanks to a case base. It consists in general in retrieving a source case $(srce, Sol(srce))$ such that $srce$ is judged similar to $tgt$ and in adapting this retrieved case in order to solve $tgt$:

Adaptation: $(srce, Sol(srce), tgt) \mapsto Sol(tgt)$ where $(srce, Sol(srce), tgt)$ is an adaptation problem and $Sol(tgt)$ is a candidate solution for $tgt$ (the relation $tgt \sim Sol(tgt)$ is not ensured since CBR is not a deductive reasoning). The adaptation step is based on adaptation knowledge that has to be acquired, which constitutes the adaptation knowledge acquisition issue.

2. AKA Principles

This section reformulates the main principle of the AKA approach proposed in [6]. The adaptation process is assumed to be composed of three steps:

1. matching: $(srce, tgt) \mapsto \Delta pb$. A representation $\Delta pb$ of the variations from $srce$ to $tgt$ is computed.
2. AK : $\Delta pb \mapsto \Delta sol$. The adaptation knowledge AK enables to build a representation $\Delta sol$ of solution variations.
3. modifying: $(Sol(srce), \Delta sol) \mapsto Sol(tgt)$ such that $\text{matching}(Sol(srce), Sol(tgt)) = \Delta sol$. $\Delta sol$ represents the variations from $Sol(srce)$ to the unknown solution $Sol(tgt)$ and thus enables to infer $Sol(tgt)$ from $Sol(srce)$.

Step 2 requires some adaptation knowledge. Conversely, if a set of pairs $(\Delta pb, \Delta sol)$ is available, some machine learning techniques may be used to learn AK. The idea is to exploit pairs of source cases to obtain such pairs of variations. If $(srce_i, Sol(srce_i))$ and $(srce_i, Sol(srce_i))$ are two source cases, let $\Delta pb_{ij} = \text{matching}(srce_i, srce_j)$ and $\Delta sol_{ij} = \text{matching}(Sol(srce_i), Sol(srce_j))$. Then, AK is learned with the training set $\{(\Delta pb_{ij}, \Delta sol_{ij})\}_{ij}$.

3. Representing and Learning Adaptation Rules

In order to make this AKA approach operational, it is necessary to be able to represent the variations $\Delta pb$ and $\Delta sol$ and to infer from ordered pairs of problems (resp., of solutions) $\Delta pb$ (resp., $\Delta sol$), which constitutes the matching process.
3.1. Representing Variations

A variation from a problem to another is the representation of a binary relation $r$ between problems. The language of such relations $r$ is denoted by $L_{Apb}$. Thus, the semantics of any $r \in L_{Apb}$ is given by its extension: $\text{Ext}(r) \subseteq L_{pb} \times L_{pb}$. $L_{Apb}$ is assumed to contain the relation $\text{T}_{Apb}$ and the relation $\langle \text{srce}, \text{tgt} \rangle$ for each ordered pair $(\text{srce}, \text{tgt}) \in L_{pb} \times L_{pb}$. The semantics of these elements is: $\text{Ext}(\text{T}_{Apb}) = L_{pb} \times L_{pb}$ and $\text{Ext}(\langle \text{srce}, \text{tgt} \rangle) = \{ \langle \text{srce}, \text{tgt} \rangle \}$.

Let $\vDash$ be the entailment relation on $L_{Apb}$ (if $r, s \in L_{Apb}$, $r \vDash s$ means that $\text{Ext}(r) \subseteq \text{Ext}(s)$) and $\equiv$ be the equivalence relation on $L_{Apb}$ ($r \equiv s$ if $r \vDash s$ and $s \vDash r$). $\vDash$ (and thus $\equiv$) is assumed to be computable. For $r \in L_{Apb}$, let $DC(r) = \{ s \in L_{Apb} | r \vDash s \}$ be the deductive closure of $r$.

Matching two problems $\text{srce}$ and $\text{tgt}$ aims at identifying the relations $r \in L_{Apb}$ relating $\text{srce}$ to $\text{tgt}$, that is, the set $DC(\langle \text{srce}, \text{tgt} \rangle)$. Since any relation $r \in L_{Apb}$ relating $\text{srce}$ and $\text{tgt}$ can be deduced from the relation $\langle \text{srce}, \text{tgt} \rangle$, matching is defined as:

$$\text{matching}(\text{srce}, \text{tgt}) = \langle \text{srce}, \text{tgt} \rangle$$

The representation of solution variations is similar: $L_{Assol}$ is the solution variation language containing $\text{T}_{Assol}$ and $\langle \text{Sol}(\text{srce}), \text{Sol}(\text{tgt}) \rangle$; $\vDash$, $\equiv$ and $DC$ are defined similarly on $L_{Assol}$; finally, matching($\text{Sol}(\text{srce}), \text{Sol}(\text{tgt})$) = $\langle \text{Sol}(\text{srce}), \text{Sol}(\text{tgt}) \rangle$.

The Symmetry Hypothesis. The symmetry hypothesis is optional in our framework. It states that for each $r \in L_{Apb}$, there exists $r^{-1} \in L_{Apb}$ such that, for each $\langle \text{srce}, \text{tgt} \rangle \in L_{pb} \times L_{pb}$, $\langle \text{srce}, \text{tgt} \rangle \in \text{Ext}(r)$ iff $\langle \text{tgt}, \text{srce} \rangle \in \text{Ext}(r^{-1})$. In particular, $\text{T}_{Apb}^{-1} \equiv \text{T}_{Apb}$ and $\langle \text{srce}, \text{tgt} \rangle^{-1} \equiv \langle \text{tgt}, \text{srce} \rangle$. A similar hypothesis can be made on $L_{Assol}$.

3.2. Representing Adaptation Rules

An adaptation rule is a piece of knowledge that can be used to solve adaptation problems $(\text{srce}, \text{Sol}(\text{srce}), \text{tgt}) \in L_{pb} \times L_{sol} \times L_{pb}$: it aims at giving pieces of information about a solution $\text{Sol}(\text{tgt})$. The adaptation rules studied in this paper are ordered pairs $(r, R) \in L_{Apb} \times L_{Assol}$ that can be interpreted as follows:

$$\text{if } \langle \text{srce}, \text{tgt} \rangle \vDash r \text{ then } \text{Sol}(\text{tgt}) \text{ is such that } \langle \text{Sol}(\text{srce}), \text{Sol}(\text{tgt}) \rangle \vDash R$$

(1)

If there exists at most one $\text{Sol}(\text{tgt}) \in L_{sol}$ such that (1) holds for any adaptation problem $(\text{srce}, \text{Sol}(\text{srce}), \text{tgt})$ then the adaptation rule $(r, R)$ is said to be specific. Otherwise, it is a general adaptation rule that is not always sufficient to solve an adaptation problem. Given two adaptation rules $AR_1 = (r_1, R_1)$ and $AR_2 = (r_2, R_2)$, $AR_1$ is said to be less general than $AR_2$—denoted by $AR_1 \preceq AR_2$—if $r_1 \vDash r_2$ and $R_1 \vDash R_2$. This means that $AR_1$ can be applied on less adaptation problems but is more accurate in the sense that the constraint on $\text{Sol}(\text{tgt})$ is stronger. The most
general adaptation rule is \((\top, \top)\). Given an adaptation rule \(AR\), the deductive closure of \(AR\) is the set \(DC(AR)\) of adaptation rules such that each \(AR' \in DC(AR)\) is more general than \(AR\) (i.e., \(AR \not\vdash AR'\)).

Under the symmetry hypothesis (on \(L_{\Delta pb}\) and on \(L_{\Delta sol}\)), an inverse rule \(AR^{-1} = (r^{-1}, R^{-1})\) can be associated to each rule \(AR = (r, R)\).

3.3. Learning Adaptation Rules

As stated in section 2, AKA consists in using as training set \(TS\) a set of pairs \((\Delta_pb, \Delta_sol)\) with

\[
\begin{align*}
\Delta_pb &= \langle srce_k, srce_\ell \rangle \in L_{\Delta pb} \\
\Delta_sol &= \langle Sol(srce_k), Sol(srce_\ell) \rangle \in L_{\Delta sol}
\end{align*}
\]

Thus, an ordered pair \(AR_{k\ell} = (\Delta_pb, \Delta_sol) \in TS\) is a specific adaptation rule that solves only the adaptation problem \((srce_k, Sol(srce_k), srce_\ell)\) in a solution \(Sol(srce_\ell)\). AKA consists in highlighting some adaptation rules \((r, R)\) that are more general than a “large” number of elements of \(TS\). More formally, with \(AR\) an adaptation rule, let

\[
support(AR) = \frac{\text{card} \{AR_{k\ell} \in TS \mid AR_{k\ell} \vdash AR\}}{\text{card} TS}
\]

Given a uniform distribution of probability on \(TS\), \(support(AR)\) is the probability that a random variable on \(TS\) entails \(AR\). Learning adaptation rules aims at finding the \(AR = (r, R) \in L_{\Delta pb} \times L_{\Delta sol}\) such that \(support(AR) \geq \sigma_s\), where \(\sigma_s \in [0; 1]\) is a learning parameter called the support threshold.

It can be noticed that if \(AR_1 \not\vdash AR_2\) then \(support(AR_1) \leq support(AR_2)\). Therefore, a presentation of the learned adaptation rules by decreasing support, starting from \((T_{\Delta pb}, T_{\Delta sol})\) whose support is 1, presents any adaptation rule before all the adaptation rules that are more specific than it.

Under the symmetry hypothesis, \(support(AR^{-1}) = support(AR)\) for each adaptation rule \(AR\). It is suggested that the two rules \(AR\) and \(AR^{-1}\) are presented together to an expert for validation.

4. Application to an Attribute-Constraint Formalism

In this section, the general framework described above is applied to an attribute-constraint formalism that extends the attribute-value formalism frequently used in CBR \[7\].

4.1. Representing Cases

A problem instance is described by the values it takes for some attributes. Problems are defined by specifying some sets of values these attributes may range over. For example, the problem in the domain of breast cancer treatment,
\[ pb = (gender, \{\text{female}\}) \land (age, [50; +\infty[) \land (s, [4; 7]) \]

represents the class of women older than 50 and for which the tumor size \( s \) is such that \( 4 \leq s < 7 \) cm.

More formally, a problem instance is an element of the Cartesian product \( \text{Inst}_{pb} = V_1 \times \cdots \times V_m \), where \( V_i \) is a set of values. In the examples, \( V_i \) is assumed to be either \( \mathbb{R} \) (the set of real numbers), \( \mathbb{Z} \) (the set of integers), \( \mathbb{B} = \{\text{true, false}\} \) (the set of Boolean) or an enumerated set (e.g. \{\text{red, green, blue}\}). The attribute \( a_i \) \((i \in \{1, 2, \ldots, m\})\) is the \( i \)th projection of \( \text{Inst}_{pb} \) on \( V_i \): \( a_i(x_1, \ldots, x_m) = x_i \).

To each \( a_i \) is associated a language of constraints \( \mathcal{L}_{a_i} = \{ \} \mathcal{C} \in \mathcal{L}_{a_i} \) is interpreted as a subset \( \text{Ext}(\mathcal{C}) \) of \( V_i \). As an example, the constraint \( [50; +\infty[ \) stated on \( V_i = \mathbb{Z} \) represents the set of integers that are greater or equal to 50. \( \mathcal{L}_{a_i} \) is assumed (1) to contain the constraints \( \top_i \) and \( \bot_i \) such that \( \text{Ext}(\top_i) = V_i \) and \( \text{Ext}(\bot_i) = \emptyset \), (2) to be closed under conjunction (if \( C, D \in \mathcal{L}_{a_i} \) there exists \( E \in \mathcal{L}_{a_i} \) such that \( \text{Ext}(C \land \text{Ext}(D) = \text{Ext}(E)) \)). Besides, it is assumed that two distinct constraints cannot denote the same set of objects: if \( \text{Ext}(C) = \text{Ext}(D) \) then \( C = D \).

A problem descriptor is a pair \( d = (a_i, C) \) where \( i \in \{1, \ldots, m\} \) and \( C \in \mathcal{L}_{a_i} \). It is interpreted as the set of problem instances which value for the \( i \)th attribute \( a_i \) in the extension of \( C \): \( \text{Ext}(a_i, C) = a_i^{-1}(\text{Ext}(C)) = \{ x \in \text{Inst}_{pb} \mid a_i(x) \in \text{Ext}(C) \} \).

Finally, a problem is an expression of the form \( pb = d_1 \land \cdots \land d_n \) where the \( d_i \) are problem descriptors. A problem is interpreted by an intersection: \( \text{Ext}(d_1 \land \cdots \land d_n) = \text{Ext}(d_1) \cap \cdots \cap \text{Ext}(d_n) \).

A problem \( pb \) is satisfiable if \( \text{Ext}(pb) \neq \emptyset \). A problem \( pb \) is under normal form if \( pb = d_1 \land \cdots \land d_m \) where, for each \( i \in \{1, \ldots, m\} \), \( d_i = (a_i, C) \) for some \( C \in \mathcal{L}_{a_i} \).

It can be shown that a problem in normal form \( pb \) is satisfiable iff it contains no occurrence of \( \bot_i \). Moreover, every satisfiable problem \( pb \) is equivalent to a unique problem \( pb' \) in normal form: \( \text{Ext}(pb') = \text{Ext}(pb) \). If \( pb = (a_1, C_1) \land \cdots \land (a_m, C_m) \) is satisfiable and in normal form, then \( a_i(\text{Ext}(pb)) = \text{Ext}(C_i) \), which justifies the notation \( a_i(pb) = C_i \). For the sake of simplicity, a conjunct of a problem of the form \( (a_i, \top_i) \) may be omitted in the notation: \( pb = (a_1, C_1) \land (a_2, C_2) = (a_1, C_1) \).

Solutions are defined analogously with a set of attributes \( A_j \) with \( j \in \{1, \ldots, n\} \).

4.2. Representing Variations

In this section, problems and solutions are assumed to be satisfiable and in normal form. The problem variation language \( \mathcal{L}_{pb} \) is defined by four constructors. The constructors \( \top_{pb} \) and \( (\text{sorce, tgt}) \) have already been defined in the general framework (cf. section 3.1). The third constructor is the conjunction: if \( r, s \in \mathcal{L}_{pb} \), then \( r \land s \in \mathcal{L}_{pb} \) and \( (pb_1, pb_2) \in \text{Ext}(r \land s) \) iff \( (pb_2, pb_2) \in \text{Ext}(r) \) and \( (pb_1, pb_2) \in \text{Ext}(s) \). The last constructor is \( a_i^\delta \), where \( a_i \) is an attribute and \( \delta \) represents a binary relation on \( \mathcal{L}_{a_i} \): \( \delta \) is chosen in a language \( \mathcal{L}_{a_i} \). The semantics of \( a_i^\delta \) is as follows: two problems \( \text{sorce} \) and \( \text{tgt} \) are related by \( a_i^\delta \) if \( a_i(\text{sorce}) \) and \( a_i(\text{tgt}) \) are related by \( \delta \). More formally:

\[
\text{Ext}(a_i^\delta) = \{ (\text{sorce, tgt}) \in \mathcal{L}_{pb} \times \mathcal{L}_{pb} \mid (a_i(\text{sorce}), a_i(\text{tgt})) \in \text{Ext}(\delta) \}
\]

For example, let us consider the formalism \( \mathcal{L}_{pb} \) based on the attributes \( a_1 = \text{gender}, a_2 = \text{age}, \) and \( a_3 = s \) (\( V_1 = \{\text{female, male}\}, V_2 = \mathbb{Z}, \) and \( V_3 = \mathbb{R} \)). It is
assumed that it is an attribute-value formalism, meaning that $L_a$ contains only $\tau_i, \perp_i$, and the singletons $\{x\}i$ for $x \in V_i$. All the $L_{\lambda \alpha}$ share the relations $= \neq$. $L_{\lambda \alpha}$ and $L_{\lambda \alpha}$ share the relations $\delta \in \{<, \leq, \geq, >\}$ on singletons defined by $\{x\} \delta \{y\}$ if $x \delta y \ (e.g., [3] < [4] since 3 < 4). Thus, if

$$srce = (gender, \{female\}) \land (age, \{65\}) \land (s, \{3\})$$
$$tgt = (gender, \{female\}) \land (age, \{70\}) \land (s, \{2\})$$
then

$$\langle srce, tgt \rangle = gender^x \land age^x \land age^y \land s^x \land s^y$$

$L_{\lambda \alpha}$ is defined thanks to four similar constructors.

The adaptation rule language is $L_{\lambda \alpha} \times L_{\lambda \alpha}$. If $AR = (r, R)$ and $AR' = (r', R')$ are two adaptation rules then $AR \land AR'$ denotes the adaptation rule $(r \land r', R \land R')$, which is consistent with the semantics of adaptation rules given by $\mathcal{L}$. Examples of $\delta$. The definition of $L_{\lambda \alpha}$ has been reduced above to the definition of a $L_{\lambda \alpha}$, for each attribute $a_i$. Although the definition of $L_{\lambda \alpha}$ is a knowledge acquisition issue, some examples of relations $\delta \in L_{\lambda \alpha}$ that may be useful are presented here.

When a set $V_i$ is associated to an algebraic structure, the latter may be reused on singletons. For example, since $\leq$ is a relation on $\mathbb{Z}$, it can be used as a relation between singletons of integers, as already mentioned above ($[3] < [4]$). Another example is related to the law $+$ on $\mathbb{Z}$, that is used to define the binary relation $\delta = add(a)$ on $\mathbb{Z}$ (for each $a \in \mathbb{Z}$): $x$ $add(a)$ $y$ if $x + a = y$.

Since $\delta$ relates two (representations of) sets, the classical binary relations between sets $(\subseteq, \subseteq, \neq, \neq)$ can be suggested for elements of $L_{\lambda \alpha}$. Additionally, let $C \subseteq L_{\lambda \alpha}$ and let $(\subseteq C \subseteq)$ be defined, for $C_1, C_2 \subseteq L_{\lambda \alpha}$ by $C_1 \subseteq C_2 \Leftrightarrow Ext(C_1) \subseteq Ext(C_2)$. $C_1$ and $C_2$ share the constraint $C$. Another relation is $\ominus$ (resp. $\ominus$) defined by $C \ominus D$ if $C \neq \tau_i$, and $D = \tau_i$ (resp. $C = \tau_i$, and $D \neq \tau_i$). Note that $a_1^x \ominus a_2^x$ and $a_1^x \ominus a_2^y$. These relations can be applied in particular when $L_{\lambda \alpha} = 2^V_i$, where $V_i$ is an enumerated set. They can also be applied when $L_{\lambda \alpha}$ is a finite set of atomic constraints organized in a hierarchy of root $\tau_i$. Finally, they can be applied on intervals on, e.g., $\mathbb{Z}$ or $\mathbb{R}$.

Other relations between intervals may be defined thanks to the reuse of Allen relations on temporal intervals $\mathcal{L}_{\lambda \alpha}$. For example, if $C_1 = [x_1, y_1]$ and $C_2 = [x_2, y_2]$ are two closed intervals on $\mathbb{R}$, $C_1 \oplus C_2$ if $y_1 < x_2$, $a = b^{-1}$, $C_1 \otimes C_2$ if $y_1 = x_2$, etc. ($b, a,$ and $m$ stand for before, after, and meets). These qualitative relations may be completed with quantitative relations such as $\text{addToBound}(a, \beta)$ defined by $C_1 \text{addToBound}(a, \beta) C_2$ if $x_1 + a = x_2$ and $y_1 + \beta = y_2$.

5. Experiments

Some experiments have been carried out in the oncology domain in order to evaluate the benefit of choosing an appropriate representation of the variations between cases.
5.1. Learning algorithm: Charm

Charm \cite{11} is a data-mining algorithm that efficiently performs the extraction of frequent closed itemsets (FCIs). Given a finite set \( \mathcal{P} \) (the set of properties or items), an itemset \( I \) is a subset of \( \mathcal{P} \): \( I \in 2^\mathcal{P} \). The input of Charm is a set of itemsets called the transactions. The support of an itemset \( I \) is the proportion \( \text{support}(I) \) of the transactions \( T \) that contain \( I \) \( (T \supseteq I) \). An itemset \( I \) is frequent with respect to the threshold \( \sigma \in [0; 1] \) if \( \text{support}(I) \geq \sigma s \). \( I \) is closed if adding to it any property alters its support: \( \text{support}(I) > \text{support}(I \cup \{x\}) \) for any \( x \in \mathcal{P} \) such that \( x \notin I \).

A benefit of using Charm lies in its efficiency with large sets of transactions. A difficulty is that, since it operates on data (and not on pieces of knowledge), a translation of the training set \( \mathcal{TS} \) into a set of transactions is required. Since the training set is constituted by specific adaptation rules \( \mathcal{AR}_{\mathcal{TS}} \) that have to be apprehended modulo the deduction relation \( \models \), the idea is to translate \( \mathcal{AR}_{\mathcal{TS}} \) into the transaction \( \text{DC(AR}_{\mathcal{TS}}) \). To be consistent with this definition, the set \( \mathcal{P} \) is set to \( \bigcup_{\mathcal{AR}_{\mathcal{TS}} \in \mathcal{TS}} \text{DC(AR}_{\mathcal{TS}}) \). Now, let \( \mathcal{AR}_1, \mathcal{AR}_2, \) and \( \mathcal{AR}_3 \) be three adaptation rules and \( I = \{\mathcal{AR}_1, \mathcal{AR}_2, \mathcal{AR}_3\} \). If there exist exactly \( n \mathcal{AR}_{\mathcal{TS}} \in \mathcal{TS} \) such that \( \mathcal{AR}_{\mathcal{TS}} \models \mathcal{AR}_1 \land \mathcal{AR}_2 \land \mathcal{AR}_3 \) then the itemset \( I \) is frequent iff \( n \geq \sigma_s \times \text{card}(\mathcal{TS}) \). If, for the same \( n \mathcal{AR}_{\mathcal{TS}} \in \mathcal{TS} \), \( \mathcal{AR}_{\mathcal{TS}} \models \mathcal{AR} \) with \( \mathcal{AR} \notin I \), then \( I \) is not closed. In other words, if \( I \) is not closed, this means that \( I \) is an over-generalization that can be specialized in the adaptation rule language without loss of the coverage of the rule in the training set.

A practical problem is raised when some \( \text{DC(AR}_{\mathcal{TS}}) \) are not finite: this leads to an infinite \( \mathcal{P} \) that Charm cannot manage. The idea is then to restrict \( \mathcal{P} \) to a finite set and each deductive closure to \( \text{DC(AR}_{\mathcal{TS}}) \cap \mathcal{P} \).

5.2. Experimental Setup

The application domain of the experiments is breast cancer treatment: a problem describes a class of patients ill with breast cancer and a solution is a treatment. A problem is represented in an attribute-constraint formalism, with 22 attributes with various constraint languages \( \mathcal{L}_a \): \( 2^\mathcal{B} \), singletons, numerical intervals, and atomic constraint hierarchies. A solution is also represented in an attribute-constraint formalism with 65 attributes. The case base contains 44 cases.

Variation languages are defined in the formalism of section \ref{4.2}, with the relations \( \delta \) given as examples. The training set \( \mathcal{TS} \) is translated into \( 44 \times (44 - 1) = 1892 \) transactions with \( \text{card} \mathcal{P} = 300 \).

5.3. Results

From this set of transactions, Charm extracted 342,994 itemsets in about 1 minute on a current PC. About 84\% of this result set corresponds to itemsets with a support lower than 3\% (i.e., generalizing less than 56 transactions).

Examples of learned rules. The extracted adaptation rules are organized in a hierarchy for \( \models \). The expert that has to validate these rules navigates in this hierarchy. For example, the expert has found the following adaptation rule:
where ctxt denotes some common context the two problems src and tgt have to share. More precisely, ctxt is a conjunction of $a_i^s$ (and, thus, $ctxt^s \equiv ctxt$), which involves that $a_i(tgt) = a_i(src)$ is a condition of the adaptation rule. Similarly, Ctxt denotes some common context for the two solutions $Sol(src)$ and $Sol(tgt)$ and is a conjunction of $A_j^s$, which involves that $A_j(Sol(tgt)) = A_j(Sol(src))$. FEC is the name of a drug for chemotherapy that is given in several cycles (attribute nb-of-FEC-cycles with values in $Z$) with a fixed dose in each cycle (attribute dose-of-FEC with values in $R$).

This rule expresses that the choice of the FEC treatment depends on the age of the patient, but does not make this dependency explicit. A navigation down the hierarchy gives the following pair of rules:

$$AR_1 = (age^b \land ctxt', nb-of-FEC-cycles^b \land dose-of-FEC^b \land Ctxt')$$

$$AR_2 = (age^a \land ctxt', nb-of-FEC-cycles^a \land dose-of-FEC^a \land Ctxt')$$

where $AR_2 \equiv AR_1^{-1}$, $ctxt' \not\equiv ctxt$ and $Ctxt' \not\equiv Ctxt$. Each of these rules states that the dependency pointed out thanks to $AR$ is decreasing: when the age increases ($age(src) > age(tgt)$) the number of cycles and the dose per cycle decrease.

The expert explains this rule by (1) the fact that the growth rate of the tumour is higher for younger patients and thus requires higher doses of chemotherapy and (2) the necessity to make a compromise taking into account the life expectation (that decreases with the age) and the life quality (that decreases with the dose of FEC).

These rules could be learned only because an expressive language was chosen to represent the variations between cases.

**Navigating in the results.** Using an expressive language to represent the variations between cases also allowed to structure the result set and to provide the expert with efficient means of navigation in it.

Among extracted rules, only a few like $AR$ were extracted with a high support value. These rules constitute a good starting point because their interpretation is quite straightforward, which makes the expert’s work much easier during the validation phase. However, they often appear to be too general and their contexts of validity need to be refined. Most of the valid rules that were found had a fairly low support. Some rules are even valid only locally, that is in a very specific context.

To discover these rules, the generality relation $\models$ on adaptation rules was used to structure the result set and provide the expert with efficient means of navigation in it. For example, a filter on the result set has been implemented that enables the expert to have access to all rules that are more specific (resp., more general) than a given rule. Using this filter, the expert has for instance been able
to visualize the set of all rules that are more specific than $AR$, among which are
the rules $AR_1$ and $AR_2$ (since $AR_1 \models AR$ and $AR_2 \models AR$).

Towards a methodology for result exploration. A methodology for the exploration of
candidate adaptation rules has emerged from these experiments. The exploration
starts with a phase of elaboration in which a search context $ctxt$ is set up together
with the expert. This search context is used to restrict the set of rules to search
into by considering only the rules that apply to a particular medical situation.
$ctxt$ takes the form of a conjunction of $\Delta = i$ with which the result set is filtered to
retain only the rules $AR$ such that $AR \models ctxt$. The expert is then provided with
means of navigation in the remaining rules and may choose to restrict his/her
search to the set of rules that are more specific than a particular rule.

6. Discussion and Related Work

Discussion. The learning process presented above is sensitive to the choice of
the variation languages $L_{pb}$ and $L_{sol}$. This choice should be made according
to a bias/variance compromise [10]. If the languages are too rich, it may prevent
from learning. For example, if the language of adaptation rules $L_{pb} \times L_{sol}$ is
closed under disjunction, then the process learns “by heart” the adaptation rule
$\bigvee AR_{\neq}$. If this language is too poor for expressing relevant adaptation rules,
these latter cannot be learned.

In the context of a given application domain, what are the relevant languages
$L_{pb}$ and $L_{sol}$? Consider, in the breast cancer treatment domain, two problems
src and tgt such that $age(src) = \{50\}$ and $age(tgt) = \{70\}$. Both relations
$r_1 = age^{50}$ and $r_2 = age^{70}$, with $\delta_1 = add(20)$ and $\delta_2 = multiplyBy(1.4)$, relate
src to tgt, but only $r_1$ is relevant for the domain experts. Indeed, the comparison of
patient ages is sometimes based on differences, never (or rarely) on ratios. Then,
choosing $r_1 \in L_{pb}$ (and, more generally, $add(\alpha) \in L_{age}$ for $\alpha \in \mathbb{Z}$) and $r_2 \notin L_{pb}$,
can be justified by the assumption that the adaptation rules must be expressed
with a language compatible with the way the expert expresses comparisons
between cases. Therefore, the choice of a language bias is a knowledge acquisition
process that is similar to the process of acquiring the vocabulary for representing
cases: the latter consists in pointing out the entities for representing cases whereas
the former consists in pointing out the entities for representing case variations.

Related Work. The approach of adaptation learning from the case base presented
in this paper is inspired from the seminal work of Kathleen Hanney and Mark
T. Keane [13], that presents some general principles and tests them successfully
in two domains. The cases of these domains are expressed in an attribute-value
formalism. More precisely, with the notations defined above, for each $i$, $V_i = \mathbb{Z}$
or $V_i$ is a finite (and rather small) interval of $\mathbb{Z}$, and $L_a$ contains only singletons.
The variations are expressed by differences, i.e., with our notations, they are
conjunctions of $\Delta^{add(\alpha)} (\alpha \in \mathbb{Z})$. Therefore, the current paper may be seen as a
formalized generalization of [13]. A difference in methodology is the following:
in [13], some adaptation rules are generated that are rather specific, and then, they
are generalized using some of the R. S. Michalski’s generalization rules [8]. In our approach, specific and general adaptation rules are generated at the same time, which enables to organize all these rules in a hierarchy for \( \forall \), that makes navigation among them easier.

Another method for learning adaptation knowledge from the case base is presented in [2], in which the use of the extracted knowledge significantly improved the CBR process. In this work, supervised learning methods such as decision trees are applied to learn predictive models from a set of adaptation cases. These models are later used to reduce the set of adaptation cases to be used in a case-based adaptation process. There are two main differences between [2] and the work presented in this paper. First, the goal of [2] is to find adaptation knowledge in the form of adaptation cases, whereas we search for adaptation rules. Second, in [2] —and also in [6]— only pairs of similar source cases are considered for the learning process, whereas we favour the selection of every distinct ordered pairs of cases. This is motivated by the will of not adding another bias to the learning process.

Finally, in [3], the authors present a knowledge discovery approach for adaptation knowledge acquisition. They use a simple description logic for representing cases, that can be likened to the attribute-constraint formalism presented above. The main difference with the work presented in this paper is the richness of the variation language—and, consequently, of the adaptation rule language—we use. Indeed, with our notations, the comparisons of two cases in [3] are only based on \( a_i^p \), \( a_i^o \), and \( a_i^c \) (with \( a_i \): a problem or solution attribute).

7. Conclusion and Future Work

This paper presents a formalization of the task of adaptation rule learning from variations in the case base and shows, through experiments in the oncology domain, the benefit of an appropriate representation of variations for the purpose of this learning process. Such a representation consists in a set of binary relations between pairs of problems and pairs of solutions. When an attribute-constraint formalism (e.g., an attribute-value formalism) is used to represent cases, these relations can be based on binary relations \( \delta \) between constraints \( C_1 \) and \( C_2 \) associated to the same attribute \( a_i \). Examples of such relations \( \delta \) are presented.

An ongoing work aims at reducing the number of candidate adaptation rules to be examined by the experts, while keeping the same adaptation knowledge. It is based on the notion of adaptation rule composition: the composition of \((r_1, R_1)\) and \((r_2, R_2)\) is the rule \((r_2 \circ r_1, R_2 \circ R_1)\), provided that \( L_{\text{Apb}} \) and \( L_{\text{Asol}} \) are closed under binary relation composition \( \circ \). If \( S_{\text{CAR}} \) is the set of candidate adaptation rules that have been learned, a generative family of \( S_{\text{CAR}} \) is a set \( G \subseteq S_{\text{CAR}} \) such that its closure under adaptation rule composition contains \( S_{\text{CAR}} \). The design of algorithms giving \( G \) with high rates \( \frac{\text{card } S_{\text{CAR}}}{\text{card } G} \) has begun. The first algorithms implemented give a rate close to 2 (i.e., the expert’s work is divided by 2).

Assessing the quality of the learned adaptation rules may be achieved by defining an objective measure of the quality of a rule, as it is usually done for association rules [4]. A future work aims at defining such measures, and studying
whether they are useful to identify the most relevant adaptation rules in the result set. For this purpose, some of the measures of association rules, such as confidence or interest, may be adapted to the context of adaptation rules.
