Rapport de recherche n° 7322 — June 2010 — 15 pages

Abstract: Point location in a triangulation is one of the most studied problems in computational geometry. For a single query, stochastic walk is a good practical strategy.

In this work, we propose two approaches improving the performance of the stochastic walk. The first improvement is based on a *relaxation* of the exactness of the predicate, whereas the second is based on *termination guessing*.

Key-words: Point location, Delaunay triangulation

This work is partially supported by ANR Project *Triangles* and Région PACA.

Marcher Plus Vite Dans une Triangulation

Résumé : La localisation d'un point dans une triangulation est un des problèmes les plus étudiés en géométrie algorithmique. Pour un petit nombre de requêtes, la marche stochastique est une bonne stratégie en pratique.

Dans ce travail, nous proposons deux idées qui améliorent les performances de la marche stochastique. La première est basée sur une *relaxation* de l'exactitude du prédicat d'orientation, tandis que la deuxième est basée sur une tentative de *divination* de la longueur de cette marche.

Mots-clés : Localisation, Triangulation de Delaunay

1 Introduction

Point location in triangulations is a classical problem in computational geometry [6]. Given a query-point q and a triangulation in \mathbb{R}^d , the problem is to retrieve the simplex containing q .

In two dimensions, locating a point has been solved in theoretical optimal $O(n)$ space and $O(\log n)$ worst-case query time a quarter of a century ago by Kirkpatrick's hierarchy [8]. However, alternative methods using simpler data-structures, with good performance in practice, are still used by practitioners. Amongst these methods, *walking* from a simplex to another using the neighborhood relationships between simplices, is a simple method which does not need any additional data-structure [4]. Walking performs well for Delaunay triangulations of evenly distributed points [5], but has a non-optimal complexity. Building on the simplicity of the walk, the Jump & Walk [9] and the Delaunay hierarchy [3] improves the complexity while retaining the simplicity of the data-structure. The main idea of these two structures is to find a good starting point for the walk to reduce the number of visited simplices.

Walking and Delaunay hierarchy are both implemented in the Computational Geometry Algorithms Library [2] (CGAL): CGAL 2D Triangulations [12] and CGAL 3D Triangulations [10]. This work aims to improve the implementation of such location strategies in CGAL.

Our Results. We describe two modifications in the stochastic walk strategy of Devillers et al. [4] which improve performance. The first one proposes a filtering scheme called *predicate relaxation*. The second one avoids to compute unnecessary *orientation tests* through a *termination guessing* strategy.

2 Preliminaries

2.1 Stochastic Walk

Given a triangulation \mathcal{T} of \mathbb{R}^d , with n vertices and m simplices, a query-point q and a simplex $\sigma \in \mathcal{T}$, the stochastic walk [4] is a strategy to locate the simplex of \mathcal{T} containing q , from σ .

First, let us define the *visibility graph* of a triangulation \mathcal{T} and a query point q . The visibility graph of \mathcal{T} and q , is a directed graph (V, E) , where $V = \{s_1, s_2, \dots, s_m\}$ is the set of simplices of \mathcal{T} , and a pair of simplices (s_i, s_j) belongs to the set of arcs E if s_i and s_j are neighbors in \mathcal{T} and the supporting plane of their common facet *separates* any point in the interior of s_i from q (in other words, segments formed by a point inside s_i and q intersect the supporting plane of the common facet of s_i and s_j). We will denote the visibility graph of \mathcal{T} and q by $\mathcal{VG}(\mathcal{T}, q)$, or simply \mathcal{VG} when there is no ambiguity. When two simplices s_i and s_j are such that $(s_i, s_j) \in \mathcal{VG}$, we will say that s_j is a *successor* of s_i .

Let us introduce three walks based on the graph \mathcal{VG} : (i) A *visibility walk* consists in repeatedly walking from a simplex s_i to an adjacent simplex s_j of s_i such that $(s_i, s_j) \in \mathcal{VG}$. (ii) Given an initial point $p \in \sigma$, a *line-walk* consists of a visibility walk such that each visited simplex intersects the segment pq . (iii)

A stochastic walk is a visibility walk where the next visited simplex, from a simplex s , is randomly chosen amongst the successors of s .

The three walks above start from σ and ends at the simplex containing q .

It is proved that arbitrary visibility walk does not always end (even in \mathbb{R}^2). The line-walk takes $O(m)$ time in the worst-case, though it is proved to take $O(\sqrt{n})$ for Delaunay triangulation of points evenly distributed in the unit square [1] and $\tilde{O}(\sqrt[3]{n})$ ¹ in the unit cube [9]. For non-Delaunay triangulation, the stochastic walk finishes with probability 1 [4], though it may visit an exponential quantity of simplices for arbitrary triangulations in the space (even in \mathbb{R}^2). In practice however, it answers points location queries faster than the line-walk [4]. Stochastic walk is the current choice of CGAL for the walking strategy [12, 10], in both dimensions 2 and 3. If the vertices of \mathcal{T} are in general position and \mathcal{T} is Delaunay, the stochastic walk visits at most $O(m)$ simplices. Furthermore, if points are evenly distributed inside the unit cube it is conjectured that the stochastic walk visits an expected $O(|pq| \cdot n^{1/d})$ simplices (see Figure 1) where $|pq|$ is the euclidean distance between a point $p \in \sigma$ and q ².

Figure 1: **Complexity Conjecture.** (a) shows the average number of visited simplices by a stochastic walk done from the simplex containing the point $(1/2, 1/2, 1/4)$, to the query-point $(1/2, 1/2, 3/4)$, in several Delaunay triangulations of $2^{10}, \dots, 2^{20}$ points evenly distributed in the unit cube. (b) shows the average number of visited simplices by a stochastic walk done from the simplex containing the point $(1/2, 1/2, 1/2-l/2)$, to the query-point $(1/2, 1/2, 1/2+l/2)$, for $l = 0.00, 0.01, \dots, 0.50$, in several Delaunay triangulations of 2^{20} points evenly distributed in the unit cube.

The primary ingredient of the stochastic walk is the *orientation test*. Given $d+1$ points $p_0(x_{00}, \dots, x_{0d-1}), \dots, p_d(x_{d0}, \dots, x_{dd-1})$, we define the orientation test as the sign of the following determinant:

$$\text{orient}(p_0, \dots, p_d) = \text{sign} \begin{vmatrix} x_{00} & \dots & x_{0d-1} & 1 \\ \vdots & \ddots & \vdots & \vdots \\ x_{d0} & \dots & x_{dd-1} & 1 \end{vmatrix} \in \{-1, 0, +1\}. \quad (1)$$

¹ $g = \tilde{O}(f(n))$ means that $g = O(f(n) \cdot h(n))$, where $h(n)$ is a polynomial of the logarithm of n .

²The $|s|$ term in the big-O is an abuse of notation. Indeed, it is a ratio of two quantities having the same unity of measure. Here is the shortcut: $|s|$ abbreviates $|s|/\delta$ (when it applies), where δ is the diameter of the domain boundary. As the domain is bounded (independently of n), then δ is a constant. And hence, we decide to just write $|s|/\delta = O(|s|)$.

Such expressions, which are the sign of a polynomial, are called *predicates*. The underlying polynomial, from which we will extract the sign for a given input, is called the *predicate polynomial* (here, the determinant of a matrix with $d(d+1)$ variables).

During the construction of \mathcal{T} , every sequence of vertices of a simplex is (by convention) positively oriented. In other words, each simplex of \mathcal{T} has $d+1$ vertices v_0, \dots, v_d , placed on p_0, \dots, p_d respectively, and $\text{orient}(p_0, \dots, p_d) = +1$.

Let q be the query point, and s be a simplex of \mathcal{T} , with vertices on points p_0, \dots, p_d . Then, an adjacent simplex s' is the successor of s iff the supporting plane of their common facet (say the facet containing the points p_1, \dots, p_d) separates p_0 and q , which is true iff $\text{orient}(q, p_1, \dots, p_d) = -1$.

Before describing the stochastic walk procedure, let us remind a well-known trick to handle queries which are not inside the convex hull of \mathcal{T} . It consists into compactifying \mathbb{R}^d into \mathbb{S}^d by: (i) adding a point at infinity p_∞ , and then (ii) gluing p_∞ and each facet of the convex hull of \mathcal{T} , forming new simplices (one for each facet). These new simplices are called *infinite simplices*.

Now we will describe the fundamental procedure of the stochastic walk algorithm, which runs for each visited simplex. Assume s is the current simplex being visited, and i is a random index chosen from $0 \dots d$.

Selecting next simplex to visit. The adjacent simplices s_j of s , opposite to the vertex v of s_j , for $j = 0 \dots d$, are tested sequentially starting at s_i (i random) to be a successor of s . The first simplex, which is a successor of s in the sequence, is selected.

Simplex found. When there is no more successors of s , then s contains q , and the remaining work is to count the number of orientation tests giving 0 as result so as to know exactly if q is inside s or on its boundary (and which piece of boundary).

Simplex not found. If s is infinite, then q is outside the convex hull of \mathcal{T} .

We will consider here a well-known modification of the basic procedure above, consisting simply into not selecting the previous visited simplex as a candidate to be the next simplex to visit [4]. This effectively avoids one orientation computation. To do this modification one needs only to remember the previous visited simplex during the walk and compare it with s_j .

The above-mentioned approach leads to an expected cost which does not exceed $(d+1)/2$ orientation tests per simplex visited during the walk. Suppose we run the procedure above on a simplex s and a query point q , then, as we skip the visited simplex, there are a total of d simplices to be tested. At the same time, in the worst case, s has only one successor³. And hence, as there is an equal $1/d$ probability that the i -th simplex tested is a successor of s , the expected number of orientation test computations is bounded by $\sum_{i=1}^d i/d = (d+1)/2$. Now the total cost of the walk depends on the expectation of the number of visited simplices (which is unknown even for points evenly distributed in the unit square). See in Figure 2 the distribution of simplices computed experimentally for some particular cases in two and three dimensions.

³ s might have no successor at all, but this case will not influence the average number of orientation tests needed, since it occurs only once, at the end of the walk.

Figure 2: **Stochastic walk size distribution.** Delaunay triangulation of 2^{20} points evenly distributed: (a) in a square, centered at $(1/2, 1/2)$; (b) in a cube, centered at $(1/2, 1/2, 1/2)$; (c) on an ellipsoid centered at $(1/2, 1/2, 1/2)$, with the x-, y- and z-axis of size $1/3, 2/3, 1$ respectively.

2.2 Exact Computation

Another relevant point here is the robustness. When computing close-to-degenerate orientation tests with an inexact number type such as `double`, the result obtained might be wrong. This has an impact e.g., when deciding whether q is located inside a simplex or on its boundary. Some nice examples can be found in Kettner et al. [7]. Getting wrong answers because of precision errors is an issue, but the real nemesis of the inexact computation is that it can lead to infinite loops. See for example the benchmarks on Delaunay computations for the DRY HANDLER model (see Figure 3) in the CGAL 3D Triangulations manual [10], which fails to terminate when using `double` number type.

Figure 3: **Infinite loop.** CGAL 3D Delaunay Triangulations enters in an infinite loop for this model (taken from the CGAL 3D Triangulations manual [10]).

The robustness issues can be solved with the exact arithmetic paradigm [11]. The exact arithmetic is provided by multi-precision type, representing rationals or even arbitrary algebraic numbers. However, these number types are very slow and should be used with an arithmetic filtering scheme. The following scheme is implemented in CGAL and works in practice. Given a predicate (such as the orientation test):

Filtering Step. The predicate polynomial is evaluated with an inexact arithmetic, and produces a result D . At the same time a bound on the maximal error between the inexact computation and the exact value is computed E . If

$|D| > E$, then the inexact computation is certified, and we are done. Otherwise the exact computation is triggered.

Exact Computation Step. If the Filtering Step did not succeeded, compute the predicate with exact number types.

2.3 Delaunay Hierarchy

The stochastic walk algorithm becomes specially useful when combined with strategies to choose a good starting simplex. In this section, we will describe one of such strategies with good practical behavior.

The Delaunay hierarchy is a point location strategy. It uses as ingredient a walking algorithm such as the stochastic walk or the line-walk. Improving the walking algorithm by a factor ρ , directly improves the Delaunay hierarchy by approximately the same factor ρ . It has an $O(n \log n)$ optimal expected complexity in the plane [3].

Given a set of n points \mathcal{P} in the space, the Delaunay hierarchy [3] constructs random samples $\mathcal{P} = \mathcal{P}_0 \subseteq \mathcal{P}_1 \subseteq \mathcal{P}_2 \subseteq \dots \subseteq \mathcal{P}_h$ such that $\text{Prob}(p \in \mathcal{P}_{i+1} \mid p \in \mathcal{P}_i) = 1/\alpha$ for some constant $\alpha > 1$. The $h+1$ Delaunay triangulations \mathcal{D}_i of \mathcal{P}_i are computed and the hierarchy is used to find the nearest-neighbor of a query q by walking at one level i from the simplex containing the nearest-neighbor of q at the level $i+1$. It is proven that if each \mathcal{D}_i has a linear number of simplices (always true in \mathbb{R}^2), the expected cost of walking at one level is $O(\alpha)$ and since the expected number of levels is $\log_\alpha n$, we obtain a logarithmic expected time to descend the hierarchy for point location.

If query-points are given one at a time, Delaunay hierarchy is one of the best solution in practice for two and three dimensions. The Delaunay hierarchy, for points in two- and three-dimensions, is implemented in CGAL [12, 10].

An interesting feature of the Delaunay hierarchy is that the average number of visited simplices during the walk on a particular level of the triangulation tends to be similar for each level when n is big enough. Figure 4 shows the distribution of the number of simplices visited during the stochastic walk done on the last level (level h) of the hierarchy for some set of points. Figure 5 shows experimentally the impact of the number of vertices on the distribution.

3 Predicate Relaxation

The visibility walk assumes that, for every visited simplex s , the next simplex to be visited is a successor of s . The correctness of the algorithm relies on the exactness of the orientation predicates. On one hand, the filtering mechanism accelerates the exact orientation test computations (see Section 2.2). On the other hand, the filtering mechanism is slower than the direct orientation test computation through inexact number types (such as e.g., double-precision floating-point numbers). In this section, we propose to extend this filtering mechanism to another level. Instead of just filtering the orientation predicate computations, we also filter the *exact* stochastic walk (the one relying on exact orientation predicates) by an inexact version of the walk using the orientation predicate computed with inexact type, and thus avoiding the filtering mechanism overhead.

Figure 4: **Delaunay hierarchy with stochastic walk.** The distribution of the number of simplices visited during the stochastic walk done on the last level of the hierarchy for 2^{20} points: (a) evenly distributed in a square, (b) evenly distributed on an ellipse, (c) evenly distributed in a cube, (d) evenly distributed on an ellipsoid, (e) on Pooran's Hand model, (f) on Galaad model. The two last models are taken from a laser scan.

The stochastic walk is mostly dependent on the performance of the orientation test, i.e. improving it also improves the whole stochastic walk performance. Allowing the orientation test to be done with inexact type, such as a **double** type, instead of an exact type: (i) on one hand, makes the computations faster; (ii) on the other hand, makes the computations possibly wrong. Using the stochastic walk with an inexact orientation test might increase the number of visited simplices (even up to an infinite number). In practice however, using

Figure 5: **Varying the number of vertices.** The distribution of the number of simplices visited during the stochastic walk done on the last level of the hierarchy for various number of random points: (a) evenly distributed in a square, and (b) evenly distributed on an ellipse, (c) evenly distributed in a cube, and (d) evenly distributed on an ellipsoid.

`double` type makes almost none of the orientation tests ever give wrong results. Therefore, a two-steps exact algorithm can be designed, where:

- The first step consists into running the stochastic walk algorithm with inexact arithmetics. To avoid a worst-case too big (sometime endless) first step, it is forced to stop after visiting a fixed maximum number of simplices. This step is called the *relaxation step*, and (i) it has a parameter which is the maximum number of visited simplices, (ii) it returns a simplex (hopefully) not too far from the solution.
- The second step consists into running the stochastic walk algorithm with exact arithmetics from the simplex returned by the relaxation step, until the solution is found. We will call this step the *solution step*.

Using this technique with a maximum of 2000 visited simplices in the relaxation step, leads to an average of 10-40 % improvement on the performance of the stochastic walk in both two and three dimensions for several input sets, see Table 1. This approach improves performance while still benefiting from the robustness of the exact computing paradigm.

4 Termination Guessing

In this section, we propose another improvement, which works when you have a suitable estimation on the distribution of the number of visited cells by the

	location	location w/ relaxation	relaxation improves by
2D			
UNIFORM SQUARE	10.5	7.77	26.2%
ANISOTROPIC SQUARE	13.2	8.18	38.0%
ELLIPSE	33.2	29.8	10.2%
3D			
UNIFORM CUBE	4.13	3.25	21.2%
ANISOTROPIC CUBE	4.79	3.79	20.7%
ELLIPSOID	11.98	9.20	23.3%
POORAN'S HAND	2.52	1.83	27.2%
GALAAD	3.03	1.89	37.7%

Table 1: **Improving performance with relaxation.** All the models have 2^{20} points. The time is computed in seconds and accounts for 2^{15} random queries inside the *convex hull* of the input points. **location** corresponds to the stochastic walk algorithm (the solution step), and **location w/ relaxation** adds the relaxation step into it. In UNIFORM SQUARE and UNIFORM CUBE, points are evenly distributed in the unit square and cube respectively. In ANISOTROPIC SQUARE and ANISOTROPIC CUBE, points are distributed in the unit square and cube respectively, such that the density $\rho \sim x^2$. In ELLIPSE and ELLIPSOID, points are evenly distributed on an ellipse and ellipsoid. POORAN'S HAND and GALAAD are real-life 3D models taken from a laser scan.

stochastic walk. This section describes only the two-dimensional case. Not only because it is simpler and extends easily, but also because it is the only dimension where we can get a significant improvement.

Suppose that the total number x of triangles visited by a stochastic walk (see Section 2.1) is known in advance. Then, during the walk, as long as the current triangle being visited t is not yet the x -th, there is no need to test if the last adjacent triangle in the sequence is a successor of t . Instead, it is directly assumed to be a successor of t . In this case, the expected number of orientation tests decreases.

However, supposing *a priori* knowledge on the total number of visited triangles during a stochastic walk, is not realistic. Instead, we “guess” a value x_0 , which is (hopefully) close to x . With this in mind, the standard stochastic walk algorithm can be modified as follows: (i) **Guessing Phase**, a constant number x_0 of triangles are visited taking into account the additional assumption that the last triangle in the sequence is directly a successor (even though this might be a wrong guess), and (ii) **Finding Phase**, the remaining triangles are visited with a standard stochastic walk. In other words, let t_0 be the current triangle being visited, t_{-1} the previous visited triangle and t_1, t_2 the two other neighbors of t_0 . One step of both Guessing Phase and Finding Phase starts by choosing randomly one of the two triangles t_1 and t_2 . Suppose that t_1 is the first triangle chosen in the random order, and t_2 the second respectively. Then one step in both Guessing Phase and Finding Phase checks whether t_1 is a successor of t_0 in \mathcal{VG} and continue the walk in case of success. The difference lies in case of failure: A step in the Guessing Phase directly continues the walk with t_2 ; whereas a step in the Finding Phase checks whether t_2 is actually a successor of t_0 to decide whether to stop walking or not. To simplify descriptions in what

follows, we denote t_{-1} by the *discarded neighbor*⁴ of t_0 , t_1 by the *first neighbor* of t_0 , and t_2 by the *second neighbor* of t_0 .

Naturally, the performance of this modification depends on the *quality* of the guess. More precisely: (i) if $x_0 < x$, the performance can only be better than the standard stochastic walk's performance, i.e. x_0 steps with the modified stochastic walk and $x - x_0$ steps with the standard stochastic walk; (ii) otherwise, the x_0 first steps use the modified stochastic walk, but goes further than x , and hence some triangles are additionally visited to reach the goal again with the standard stochastic walk. Two exceptions need to be taken into account:

Hitting the convex hull. If during the Guessing Phase, we reach an infinite triangle t_0 from a triangle t_{-1} , then we passed through a facet of the convex hull. In this case, if t_0 is: (i) the first neighbor of t_{-1} , then q is outside the convex hull; (ii) the second neighbor of t_{-1} , then we check if t_0 is a successor of t_{-1} . If t_0 is indeed a successor of t_{-1} , then again q is outside the convex hull; otherwise, the Finding Phase begins from t_{-1} .

Remembering previously visited triangle. As described before, when visiting a triangle t_0 from a triangle t_{-1} , t_{-1} is a discarded neighbor of t_0 , and thus it is not considered as a possible next triangle to visit. Suppose the algorithm is switching from the Guessing Phase to the Finding Phase. When the only successor of t_0 in \mathcal{VG} is exactly t_{-1} (visited during the Guessing Phase), the algorithm might deduce wrongly that t_0 contains q , see Figure 6. This happens because t_{-1} is discarded from the list of potential next triangles to visit. To fix this, it is sufficient to not discard t_{-1} when switching from the Guessing Phase to the Finding Phase. Since we assume that x_0 is chosen to be smaller than x , it is reasonable to make t_{-1} the last one amongst the neighbors of t_0 to be tested.

Figure 6: **Switching from the Guessing Phase to the Finding Phase.** After x_0 steps, termination guessing stops at t . The previously visited triangle and t share edge c . In the next step: the adjacent triangles of t with common edges a and b are not successors of t ; the only alternative is the previous visited triangle, but it is skipped, and thus, the triangle is wrongly deduced to be containing q .

Given x and $x_0 > 0$, the expected amount of orientation tests depends on the number of successors per visited triangle during the walk. We will evaluate now, the expected total number of orientation tests computed by the modified stochastic walk. Suppose, the following two scenarios where q is in the interior of the convex hull of the domain:

Points on two parallel lines. In this case, for each triangle t during the walk, there is: (i) one adjacent triangle which has been visited, (ii) one adjacent

⁴The meaning of the word “discard” here, is that the neighbor is discarded from the possible candidates to be visited next.

triangle which is infinite, and (iii) one adjacent triangle which is closer to q . And thus, for each t , there are only one successor. In the first step, we need to do an expected number of at most $5/3$ orientation tests: $1/3$ probability that the first, second and third adjacent triangle is a successor of t respectively ⁵. In the next $x_0 - 1$ steps, as we remember the previously visited triangle, and we use termination guessing, we have exactly $x_0 - 1$ orientation tests to do. Now, we will pessimistically assume that if x_0 goes $x - x_0$ steps away from the cell containing the query, then it will take $x - x_0$ additional steps to return back. In this case, as we are not doing termination guessing anymore, there is $1/2$ probability that the first adjacent triangle checked is a successor of t , and $1/2$ probability that the last one is a successor of t . That gives an expected $3/2 \times |x - x_0|$ expected orientation test computations. We can summarize this as follows. In the case of points on two parallel lines, for a given x , the expected total number of orientation tests computed by the modified stochastic walk, using x_0 as guess, is given by:

$$F(x, x_0) = x_0 + \frac{2}{3} + \frac{3}{2}|x - x_0|. \quad (2)$$

Points on an ellipsoid with different axis size should follow the same analysis.

Points uniformly distributed in the unit cube. In this case, for each triangle t during the walk, considering that q is sufficiently far away from s , there is a $1/2$ probability that t has only one successor, see Figure 7.

Figure 7: **Number of successors.** If q is inside the light-grey regions, then the number N of successors of t is 2. Otherwise, $N = 1$. If q is far from t , the probability that $N = 2$ is approximately the sum of the angles divided by the total angle of the unit circle, i.e. $\pi/2\pi = 1/2$.

The same analysis as above gives that, in the case of points evenly distributed in the unit square, for a given x , the expected total number of orientation tests computed by the modified stochastic walk, using x_0 as guess, is given by:

$$F(x, x_0) = x_0 + \frac{2}{3} + \frac{5}{4}|x - x_0|. \quad (3)$$

⁵As we are using termination guessing, when the first triangle is not a successor of t , we check only one additional adjacent triangle to be a successor of t . And thus, we have $5/3 = 1/3 \times 1 + 2/3 \times 2$ expected orientation test computations.

Now, suppose that x is a random variable with distribution $P(x)$ for $x \in \mathbb{N}$. Then, for a given x_0 , the expected total number of orientation test computations is given by

$$E(x_0) = \sum_{i=0}^{\infty} F(x, x_0) \cdot P(x). \quad (4)$$

And then, the best guess x^* , is given by $x^* = \arg \min_{i \in \mathbb{N}} E(i)$.

Again, it is not realistic to assume that P is known. However in this case, the distribution P can be estimated on-line by updating a histogram with the total number of visited triangles per query. When the estimation is (heuristically) good enough, then x^* is computed, and the modified stochastic walk is used instead. Computing x^* can be done efficiently by a binary search on $E(x)$, since E has only one minimum. Figure 8 shows x^* for the case of points evenly distributed in the unit square, and points following the distribution $\rho(x, y) = x^2$ in the unit square.

Figure 8: **A bound on the expected number of orientation tests in function of x_0 .** The distribution is computed, then $E(x_0)$ is estimated for points: (i) evenly distributed in the unit square, (ii) following the distribution $\rho(x, y) = x^2$ in the unit square.

We implemented this algorithm in both two and three dimensions, and the actual number of orientation tests computed, for several inputs, are summarized in Figure 9.

In Figure 8, the value of x^* obtained by Eq.(3), Eq.(4), and P (computed experimentally) coincides with the value of x^* obtained when running the implementation in Figure 9, for points evenly distributed in the unit square. We can see that the bound in Figure 8 is rather pessimistic compared with what happens in practice. Also from Figure 8, in 2D, the number of orientation tests computed is considerably smaller when using the termination guessing (around 25%); specially in the case of points on an ellipse which is in accord with the theory, since the standard stochastic walk is less efficient ($3/2$ orientation tests per triangles visited in average for points an ellipse, and only $5/4$ orientation tests per triangles for points evenly distributed in the square). As $E(x_0)$ is monotonically decreasing for $x_0 \leq x^*$, then for any $x_0 \leq x^*$ the performance is better than the standard stochastic walk ($x_0 = 0$). And hence, e.g., just skipping the last few orientation tests, leads to a speed-up.

Figure 9: **Actual number of orientation tests per x_0 with termination guessing.** The figure above shows the actual number of orientation tests computed with termination guessing for various values of x_0 , in a Delaunay triangulations of 2^{20} points: (a) left, evenly distributed in the unit square; center, following the distribution $\rho(x, y) = x^2$ in the unit square; right, evenly distributed on an ellipse; (b) left, evenly distributed in the unit cube; center, following the distribution $\rho(x, y, z) = x^2$ in the unit cube; right, evenly distributed on an ellipsoid. For (a), the query is located in $(1/2, 3/4)$ and starts from the triangle enclosing $(1/2, 1/4)$; for (b), the query is located in $(1/2, 1/2, 3/4)$ and starts from the tetrahedron enclosing $(1/2, 1/2, 1/4)$.

Choosing a small value of x_0 (such as 2 or 3), should be useful for Delaunay hierarchies, since, as shown in Figures 4 and 5, the distribution of visited triangles is concentrated in low values of x for different values of n . However, experiments showed that the improvement in this case is rather weak, and hardly represent more than 5% of the total time.

5 Conclusions

We proposed two modifications of the stochastic walk strategy which improves performance up to a factor of 40%. Both modifications are practical and simple to implement. Also, if the predicate relaxation works well for an input set, then the performance gains of the two methods are cumulative. We will submit the predication relaxation for integration in the library. As the termination guessing needs fine-tuning and CGAL is a general purpose library, we decide to not submit it yet.

Unfortunately, little are known about the exact distributions of the stochastic walk (even tight bound on the average). We wish to mention this theoretical advancement as a well-suited future work.

Acknowledgments The authors wish to thank Aim@shape for providing the realistic models, ANR Project *Triangles* and Région PACA for their support.
