On Single-Scanline Camera Calibration
Radu Horaud, Roger Mohr, and Boguslaw Lorecki

Abstract—A method for calibrating single scanline CCD cameras is described in this paper. We show that the more classical 2-D camera calibration techniques are necessary but not sufficient for solving the 1-D camera calibration problem. We propose a model for single scanline cameras, and we provide a two-step procedure for estimating its parameters. We also show how the extrinsic camera parameters can be determined geometrically without making explicit the intrinsic camera parameters. The accuracy of the calibration method is analyzed through an application example.

Index Terms—Camera calibration, cross-ratio, intrinsic and extrinsic camera parameters, linear least squares estimation, perspective projection, single scanline CCD cameras.

I. INTRODUCTION

In many applications of computer vision, 1-D (single scanline) cameras may replace 2-D (matrix) cameras. Inspection of parts, for example, is a task that requires, among others, two main constraints: efficiency and accuracy. Linear cameras fit both these constraints for the following reasons. First, the 1-D signal they provide is easier and faster to process than 2-D images. Second, the current size of a linear camera may reach 4096 pixels. Compare this with the size of a matrix camera (at an affordable price) of 512 × 512 pixels. We conclude that linear cameras are well suited for tasks that do not involve high-level processing and for which accuracy is a crucial issue, such as inspection.

More generally, the calibration of a camera allows one to establish a relationship between image measurements and 3-D measurements. This relationship is useful for a variety of tasks:
- 3-D reconstruction using either passive stereo or active ranging,
- mobile-robot navigation,
- 3-D object recognition by matching a CAD model to 2-D data,
- hand-eye calibration that allows one to relate measurements in the camera-centered frame to the robot-centered frame, and
- 3-D inspection of parts.

The calibration of a matrix camera has received a lot of attention in the past, and robust techniques are now available [3]-[5], [8], [9]. Surprisingly enough, to the best of our knowledge, linear-camera calibration is not described in the technical literature. In [2], a couple of single scanline CCD cameras are used for detecting obstacles in front of a mobile robot. A cylindrical lens that is placed in front of each camera widens the field of view without modifying the geometry of the sensor, e.g., Fig. 1. Motion self-calibrates the camera pair for the purpose of stereo. However, it is assumed that the viewing planes (see below) associated with the two cameras are coplanar.

The calibration method described here could be used to verify that the two cameras are actually coplanar.

In this paper, we show that currently available camera calibration methods are necessary but not sufficient for solving the linear-camera calibration problem. We propose a two-step camera calibration method that uses the classical approach in conjunction with the cross-ratio, a well known projective invariant [6]. We define a camera-centered coordinate frame and determine the extrinsic parameters of the camera, that is, the rigid transformation between the calibrating coordinate frame and the camera frame.

II. TWO-DIMENSIONAL CAMERA CALIBRATION

Central projection or the pin-hole model is a good approximation of the geometry of an imaging system. Using central projection, the 2-D camera calibration problem is described by the following equations [3]. [1]:

\[
\begin{align*}
\mathbf{u} &= \frac{m_{11}X + m_{12}Y + m_{13}Z + m_{14}}{m_{31}X + m_{32}Y + m_{33}Z + m_{34}} \quad (1) \\
\mathbf{v} &= \frac{m_{21}X + m_{22}Y + m_{23}Z + m_{24}}{m_{31}X + m_{32}Y + m_{33}Z + m_{34}} \quad (2)
\end{align*}
\]

These equations describe a point defined in a calibrating (world) frame projected onto the image. The world coordinates of the 3-D point are \( X, Y, \) and \( Z, \) and the image coordinates of its projection are \( u \) and \( v. \) Notice that these equations have another possible interpretation. They describe the line passing through the center of projection of the camera and through an image point, in world coordinates. The 2-D camera calibration problem is the problem of determining the parameters \( m_{ij} \) through \( m_{34}. \) If at least six correspondences are available, and noticing that the \( m_{ij} \)'s are defined up to a scale factor, the calibration problem becomes a linear optimization problem [3]. We mean by correspondence \( \mathbf{i} \) that the set \( \{X_i, Y_i, Z_i, u_i, v_i\} \) is known: the coordinates of a 3-D point are...
known in world coordinates and its 2-D projection is known in image coordinates as well.

III. ONE-DIMENSIONAL CAMERA CALIBRATION

The best way to describe a single scanline (or linear) camera is to think of a matrix camera for which only one line of pixels is active. A 3-D point projects onto this linear image at pixel $u$ obeying (1). This equation can be written in matrix form:

$$
\begin{bmatrix}
X \\
Y \\
Z \\
1
\end{bmatrix} =
\begin{bmatrix}
m_{11} & m_{12} & m_{13} & m_{14} \\
m_{21} & m_{22} & m_{23} & m_{24} \\
m_{31} & m_{32} & m_{33} & m_{34} \\
1 & 1 & 1 & 1
\end{bmatrix}
\begin{bmatrix}
u \\
1
\end{bmatrix}.
$$

(3)

This projective transformation can be further decomposed into a rigid transformation (rotation and translation) followed by a one dimensional projection:

$$
\begin{bmatrix}
m_{11} & m_{12} & m_{13} & m_{14} \\
m_{21} & m_{22} & m_{23} & m_{24} \\
m_{31} & m_{32} & m_{33} & m_{34} \\
1 & 1 & 1 & 1
\end{bmatrix}
\begin{bmatrix}
r_{11} & r_{12} & r_{13} & r_{14} \\
r_{21} & r_{22} & r_{23} & r_{24} \\
r_{31} & r_{32} & r_{33} & r_{34} \\
0 & 0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
\alpha_u \\
u_0 \\
0 \\
0
\end{bmatrix}
= \begin{bmatrix}
m_{31} & m_{32} & m_{33} & m_{34} \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
r_1 \\
r_2 \\
r_3 \\
t
\end{bmatrix}
$$

where $\alpha_u$ and $u_0$ describe the projection, $R = [r_{ij}]$ is an orthonormal matrix describing the rotation, and $t = (t_1 t_2 t_3)$ is a translation vector. One can easily notice that $m_{31} = r_{31}$, $m_{32} = r_{32}$, and $m_{33} = r_{33}$, and that we have

$$
m_{31}^2 + m_{32}^2 + m_{33}^2 = 1
$$

(4)

since $R$ is an orthonormal matrix. This constraint is used in [3] to obtain a better estimation of the projection parameters.

Moreover, in order to be seen by the camera, the 3-D point is constrained to lie in the viewing plane, the plane defined by the center of projection and by the active line of pixels, e.g., Fig. 1. Without loss of generality, the equation of the viewing plane can be written as

$$
X = \rho Y + \gamma Z + r.
$$

(5)

By substituting (5) into (1), renaming variables, and noticing that (1) describing a projection is defined up to multiplicative term, we obtain

$$
u = \frac{n_1 Y + n_2 Z + n_3}{n_4 Y + n_5 Z + 1}.
$$

(6)

Equations (5) and (6) define the linear-camera model, that is, they describe the line passing through the center of projection and an image pixel, in world coordinates. This line is also called the viewing line.

This model has eight parameters associated with it: $n_1$, $n_2$, $n_3$, $n_4$, $n_5$, and $\rho$, $\gamma$, and $r$. The problem of determining the camera model is the problem of estimating these parameters. In the Appendix, we prove that eight parameters are sufficient for describing a linear-camera model. Hence, the linear-camera calibration problem is twofold:

- Estimate the parameters $n_1$, $n_2$, $n_3$, $n_4$, and $n_5$. If at least five correspondences are available (five sets $(Y_i, Z_i, u_i)$), this may be mapped into a linear optimization problem similar to the case of 2-D camera calibration.
- Estimate $\rho$, $\gamma$, and $r$. These parameters can be estimated if and only if world points belonging to the viewing plane are provided.

Alternatively, one may use (1) and (4) instead of (6), as done in [3]. The drawback is that the camera model is described by 11 parameters instead of eight.

Interesting enough, the linear-camera calibration problem is similar to the problem of calibrating an active range sensor [1]. In the latter case, two calibration steps are also necessary: one for calibrating the camera and one for determining the equation of the plane of light in world coordinates. However, in our case, the two steps are independent while in the case of active range-sensing they are not.

IV. A TWO-STEP CALIBRATION METHOD

We begin by describing the structure of the calibrating object used by our method. The choice for this structure will soon be made clear. The calibrating object is shown on Fig. 2. It consists of four coplanar straight lines, $\text{D}_1$, $\text{D}_2$, $\text{D}_3$, and $\text{D}_4$. The first three are mutually parallel, and $\text{D}_4$ makes an angle with the direction of these three. The equations of these lines are known in the calibrating (world) coordinate frame, defined as follows: the origin of this frame is not constrained to a particular position. The $X$ axis is parallel to $\text{D}_1$, and the $Y$ axis is perpendicular to $\text{D}_1$. The $Z$ axis is perpendicular to the $X - Y$ plane. In this frame and in the plane $Z = 0$, the equations of the four lines can be written as

$$
\begin{align*}
Y &= 0 \\
Y &= \alpha \\
Y &= \beta \\
Y &= \gamma X + \delta
\end{align*}
$$

where the parameters $\alpha$, $\beta$, $\gamma$, and $\delta$ are fixed and determine the structure of the calibrating object.

A. Estimating $n_1$, $n_2$, $n_3$, $n_4$, and $n_5$

When a linear camera "looks" at this object, it "sees" four image points $a$, $b$, $c$, $d$, which are the projections of $A$, $B$, $C$, $D$, the intersections of the viewing plane with $\text{D}_1$, $\text{D}_2$, $\text{D}_3$, $\text{D}_4$, e.g., Fig. 2. Notice that the $X$ coordinates of $A$, $B$, $C$, $D$ need not be known. Due to the structure of the calibrating object and the particular choice of the calibrating frame, the $Y$ and $Z$ coordinates of $A$, $B$, $C$ are known independently of the position and orientation of the viewing plane (with respect to the calibrating frame).

Therefore, one can establish the following correspondences: $(Y_A, Z_A, u_a)$, $(Y_B, Z_B, u_b)$, and $(Y_C, Z_C, u_c)$. By moving the
calibration object in the $Y$ direction and/or in the $Z$ direction with known increments, one can establish three correspondences at each new position of the calibrating object. Each correspondence is defined by

$$Y_i n_1 + Z_i n_2 + n_3 - a_i Y_i n_4 - a_i Z_i n_5 = u_i. \quad (7)$$

For $n$ such correspondences, $n \geq 5$, we obtain

$$\begin{bmatrix}
Y_1 & Z_1 & 1 & -u_1 Y_1 & -u_1 Z_1 \\
\vdots & \vdots & \vdots & \vdots & \vdots \\
Y_n & Z_n & 1 & -u_n Y_n & -u_n Z_n
\end{bmatrix}
\begin{bmatrix}
u_1 \\
v_2 \\
\vdots \\
v_n \end{bmatrix} = 
\begin{bmatrix}
u_1 \\
v_2 \\
\vdots \\
v_n \end{bmatrix}. \quad (8)$$

This is an overconstrained system of $n$ linear equations in five unknowns of the form \(AX = B\). By premultiplying with the transpose of \(A\), we obtain a linear system with $5$ equations and $5$ unknowns: \(A'AX = A'B\). Notice that \(X = (A'A)^{-1}A'B\) is the optimal solution in the least squared sense and that the covariance matrix associated with the estimated solution may be computed as well [7, pp. 528–532]. Since we wish to compute not only the parameters \(n_1\) through \(n_5\) but also the covariance matrix, it is most convenient to use Gauss–Jordan elimination to perform the linear algebra.

**B. Estimating \(p, q, r\)**

In order to estimate \(p, q,\) and \(r\), sets of 3-D coordinates of points belonging to the viewing plane must be available. Obviously a linear camera cannot provide point-to-point correspondences in the general case. The structure of the calibrating object has been purposely designed to be able to provide, in conjunction with the camera, 3-D data that can be used to find a solution.

We recall the definition of the cross-ratio of four collinear points:

$$\text{cross-ratio}_{A, B, C, D} = (A, B, C, D) = (CA/DB)/(DA/DB)$$

where \(CA\) being the algebraic distance from \(C\) to \(A\). The fundamental property of the cross-ratio is that it is invariant by central or parallel projection. Therefore, we have

$$(A, B, C, D) = (a, b, c, d).$$

We consider a virtual line \(D_i\), parallel and coplanar with \(D_1, D_2, D_3\), and \(D_4\) passing through the point \(D_i\). These four parallel lines \(D_1, D_2, D_3, D_4\), and \(D_i\), intersect the \(Y\) axis in \(A', B', C',\) and \(D'\). From the projective invariance of the cross-ratio, we have

$$(A, B, C, D) = (A', B', C', D')$$

and hence

$$(C'A'/C'B')/(D'A'/D'B') = (ca/fb)/(da/db).$$

We conclude that if the linear camera sees simultaneously \(D_1, D_2, D_3,\) and \(D_4\) (in fact, the camera sees the points \(A, B, C,\) and \(D\)), then one is able to compute the cross-ratio \(r, r = (a, b, c, d)\) from the image measurements and therefore determine the position of \(D'\) along the \(Y\) axis, say \(Y = \lambda\). We have

$$r = (C'A'/(C'B'))/(D'A'/(D'B'))$$

and

$$\lambda = \frac{\alpha \beta}{\rho \alpha + (1 - \rho) \beta}.$$
Without loss of generality, we suppose that the camera has 1024 pixels, \( u_1 \) through \( u_{1024} \). The viewing line passing through the central pixel \( u_{512} \) is given by the following equations (see (5) and (6)),

\[
(n_1 - n_4 u_{512}) Y + (n_2 - n_5 u_{512}) Z + n_3 - u_{512} = 0
\]
\[
-X + pY + qZ + r = 0.
\]

The direction of this line \( \mathbf{l} \) is given by the cross-product of the normals to these two planes. These two normals are

\[
\mathbf{N}_1 = (n_1 - n_4 u_{512} \quad n_2 - n_5 u_{512})^t
\]
\[
\mathbf{N}_2 = (-1 \quad p \quad q)^t.
\]

The axes of the camera frame have the following unit direction vectors:

\[
\mathbf{i} = \frac{\mathbf{N}_1 \times \mathbf{N}_2}{\mathbf{N}_1 \times \mathbf{N}_2}
\]
\[
\mathbf{m} = \frac{\mathbf{N}_2}{\mathbf{N}_2}
\]
\[
\mathbf{n} = \mathbf{i} \times \mathbf{m}.
\]

These three vectors determine the rotation matrix associated with the rigid transformation

\[
\mathbf{R} = (\mathbf{i} \mathbf{m} \mathbf{n}).
\]

To determine the translation one may easily notice that all the viewing lines pass through the center of projection, in particular, the viewing lines associated with the first and last pixels (and any other two pixels). The coordinates of \( F \) are given by combining two viewing-line equations

\[
(n_1 - n_4 u_{1}) Y_F + (n_2 - n_5 u_{1}) Z_F + n_3 - u_{1} = 0
\]
\[
(n_1 - n_4 u_{1024}) Y_F + (n_2 - n_5 u_{1024}) Z_F + n_3 - u_{1024} = 0
\]
\[
-X_F + pY_F + qZ_F + r = 0.
\]

It is worthwhile to notice that the extrinsic parameters embedded by the rotation matrix \( \mathbf{R} \) and the translation vector \( \mathbf{l} \) have been determined geometrically without making explicit the intrinsic camera model.

VI. RESULTS AND CONCLUSION

Using the method described here and for one calibration, we used 150 measurements to estimate the \( n_i \)'s and 50 measurements to estimate \( p \), \( q \), and \( r \). Indeed, for each position of the calibration object with respect to an initial position, points \( A \), \( B \), and \( C \) are used for estimating \( n_i \) through \( n_6 \), while the point \( D \) is used for estimating \( p \), \( q \), and \( r \); see Section IV.

An important merit of any calibration procedure is its accuracy. Tables I and II summarize the results of one calibration. In addition, the covariance matrices are provided with the values obtained for the sought parameters [7].

The only parameter not accurately estimated is \( r \), the intersection of the viewing plane with the \( X \) axis. The reason for this problem is that the set of 3-D points used for estimating the viewing plane equation were not evenly distributed in this plane; they were concentrated. One way to overcome this problem is to consider a-calibrating object that has more than one oblique line.

APPENDIX

WHY EIGHT PARAMETERS?

The single-scanline camera model describes the central projection of a 3-D point onto a straight line (the linear set of pixels). The 3-D point generally being described in a world frame that is different from the camera frame, a frame change must be performed prior to the projection. Six parameters are necessary to describe the frame change transformation: three for rotation and three for translation.

The camera frame is chosen such that the linear image is perpendicular to one of the axes (the optical axis) and the origin is at the center of projection. Two parameters are necessary to describe this central projection (four in the case of a 2-D image): the pixel coordinate of the intersection of the image with the optical axis and the ratio of the focal length with the pixel size.

It is straightforward to see that the variation of the value of one of these eight parameters modifies the camera model and that this modification cannot be compensated by the variation of any of the remaining parameters. Hence, the model is described by eight independent parameters.

Performance Evaluation of a Class of M-Estimators for Surface Parameter Estimation in Noisy Range Data

Muhammad J. Mirza and Kim L. Boyer

Abstract—Depth maps are frequently analyzed as if the errors are normally, identically, and independently distributed. This noise model does not consider at least two types of anomalies encountered in sampling: a few large deviations in the data, often thought of as outliers, and a uniformly distributed error component arising from rounding and contaminants. This noise model is appropriate under a Gaussian noise assumption, can be excessively heavy tailed, represents the outliers more realistically. This work extends when the weights are obtained by a simple linearization and then embedded for the purpose of systematic grouping errors as well as random measurement errors.

After selecting an appropriate model for the underlying surface, the most popular approach is to use least squares analysis to estimate the model parameters. This presupposes that errors in the data are normally, identically, and independently distributed. However, the first two of these assumptions are frequently inappropriate. In fact, the error distributions are more likely to be leptokurtic and/or contaminated by occasional anomalous values, or outliers.

The outliers play havoc with estimators using ordinary least squares. Even without outliers problems occur because range images consist of noisy quantized samples of object surfaces, and quantization errors are not Gaussian distributed. To remedy the problem of nonnormal errors, new statistical techniques known as robust methods have been developed that are insensitive to such departures in the data [7], [8].

Mirza and Boyer [1], [2] have developed a robust sequential estimator (RSE) based on maximum likelihood analysis for a wide class of nonnormal distributions. The distinguishing feature of this estimator is that uses W-estimation for initial estimates while using W-estimation for sequential updates (these terms will be explained in the following discussion). The specific implementation in [1] and [2] was based on a t distribution error model. This is a novel robust approach since it models the errors by a heavy tailed distribution that is more prone to produce outliers, and it achieves computational efficiency through sequential updating. Our weighted sequential scheme is different from other sequential approaches, e.g., Kalman filtering, which is optimal only for Gaussian noise. Recursive QR updating [13] rejects the possible outliers and then equally weights the accepted observations. Our algorithm assigns weights to each observation based on a t distribution error model and, hence, rejects the outliers by down weighting. The other outstanding feature of the RSE is that it considers the outliers as unimportant rather than as unusual observations. This fact has been effectively exploited in our work on simultaneous organization and parametrization of surfaces in range data.

The selection of the t distribution error model for the RSE was based primarily on intuition, and no thorough experimental investigation of other error distribution models and maximum-likelihood estimators (M-estimators) was undertaken. This work, then, follows up by investigating a variety of well known M-estimators (a class of robust estimator defined below) when embedded in the same RSE. We compare them on the basis of efficiency and performance for different known and unknown noise models.
